This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

**Usage guidelines**

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

+ *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.

+ *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.

+ *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.

+ *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

**About Google Book Search**

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at `http://books.google.com/`

# PREFACE TO THE FOURTH EDITION

The present edition of the STANDARD HANDBOOK for ELECTRICAL ENGINEERS, preparation of which was undertaken early in the year 1913 under the editorial direction of the writer, embodies so many changes and so much new matter that it is virtually a new book, retaining, however, the general features and scheme of arrangement which have received extensive endorsement in the prior editions. As heretofore, the STANDARD HANDBOOK is intended primarily as a reference book of practical information and data for practising engineers and a supplement to the standard text-books employed in teaching electrical engineering in colleges and universities. It is well recognized that limitations of space within a single volume of this character, even of the present size, render it impossible to treat each subject exhaustively. Our efforts have been concentrated chiefly on the task of presenting as much information and data of a practical nature as space would permit, reducing descriptive matter to the reasonable minimum and relying on references to standard works for extended dissertations on theory and highly special topics. Perhaps the most difficult task of all, in the present revision, was that of keeping the subject matter within the confines of a volume which would not be impossible in either the physical or the commercial sense.

Owing to the numerous advances in electrical science and the electrical arts since the appearance of the third edition in 1910, and owing also to certain criticisms which had been made concerning the earlier editions, the Publishers approved at the outset a broad and liberal editorial policy which greatly facilitated the work and minimized the burdens of a task that at best is a difficult one.

The first problem was the rearrangement of the sections for the purpose of securing a rational classification of major subjects and insuring a well-balanced presentation. A great deal of time was spent in consideration of this question before undertaking the details of the work. In the same manner much attention was given to the grouping of subjects under minor divisions in each main section, in order that the

357922 Digitized by Google

information on each subject might be presented in reasonably compact form, and at the same time be easily located.

Thus each numbered paragraph opens with a descriptive title or phrase in bold-faced type, while in other respects the use of such type has been limited to subheads and important key words which should catch the eye upon a casual glance over the pages. An entirely new feature is the consistent use of subheads throughout each section and the grouping of these on each section title page, for the double purpose of describing the contents in some detail and serving as a ready guide to any particular subdivision or minor subject. This general scheme of presentation is not intended to relieve the necessity for a thorough and complete index, but rather to supplement the latter and make the book of maximum usefulness. Another new feature is the addition of bibliographies at the end of each section or subsection, and the insertion of numerous references throughout the text to more extended or specialized literature.

In retaining the sectional or unit system of arranging a reference work of this character, both the Editor and the Publishers are convinced from past results that there is no other form of arrangement which is so well suited to the production of a useful and convenient handbook, or which makes possible the segregation of all the material relating to each subject, presented in logical sequence and so displayed as to give it the desired prominence.

Sections 1 to 5 inclusive cover the same general ground as in the third edition, but have been almost completely rewritten and considerably extended.

Sections 6 to 9 inclusive embrace the same subjects as Sections 6 to 8 in the third edition, but conform to a revised classification which is believed to be preferable to the former arrangement. These sections have also been entirely rewritten and substantially enlarged.

Section 10 covers the same general subject matter as the corresponding section in the last edition, but is entirely rewritten and greatly enlarged.

Sections 11 and 12 cover the same ground as Section 11 in the third edition, but are entirely new and much more comprehensive.

Section 13 replaces Section 18 in the old edition, being entirely

Digitized by Google

rewritten; Section 14 replaces Section 12, with entirely new material; Section 15, Industrial Motor Applications, is a new section with entirely new subject matter.

Section 16 covers the ground of Section 13 in the third edition, and has been thoroughly revised. Section 17, Electric Vehicles, and Section 18, Electric Ship Propulsion, are both new sections.

Section 19 replaces Section 14 in the third edition, many portions of it being rewritten. Section 20 takes the place of old Section 9 with new material, and Section 21 replaces old Sections 15 and 16, also rewritten and altered somewhat in scope.

Section 22 takes the place of Section 17 in the old edition, with almost exclusively new material. Section 23, Mechanical Section, is a new section; Section 24 corresponds to Section 19 in the last edition; Section 25, General Engineering Economics and Central Station Economics, is entirely new. Section 20 in the former edition has been abandoned and its contents, or their revised equivalents, have been distributed among other sections.

The Editor takes this occasion to thank his numerous associates for their cooperation and enthusiasm throughout a long and difficult task, and to acknowledge the painstaking efforts of the Publishers concerning the mechanical features and their patience over the unexpected but seemingly unavoidable delays in completing the editorial portion of the work. Acknowledgment is also due to my assistant, Mr. J. C. Bogle, who has painstakingly performed a large share of the routine editorial work; to Mr. Walter Jackson, Associate Editor of the *Electric Railway Journal*, who has read the complete proofs before going to press; and to Mr. O. A. Kenyon, who has prepared the index.

FRANK F. FOWLE,
*Editor-in-Chief.*

CHICAGO, *June* 15, 1915.

# PREFACE TO THE THIRD EDITION

The preface to the first edition of the STANDARD HANDBOOK, which appears on another page, describes the "unit" system on which the work was developed. The present edition, the publishers believe, is somewhat of a triumph for this system. The thorough revision of a book of this size, when manufactured according to the usual plan, is commercially impossible except at long intervals when the changes in the art become so great as to demand an entirely new book. The "unit" system employed in the STANDARD HANDBOOK permits thorough revision in part or as a whole without any of the usual limitations.

In the present revision the authors of the various sections were allowed a free hand in so far as mechanical details were concerned. They were not restricted in space or compelled to cut and prune material to fit pages. The result is a book that has been thoroughly revised from cover to cover so that it could be fairly called a new STANDARD HANDBOOK.

The following synopsis gives a brief outline of the changes and additions that have been made to the various sections.

Section 1, Units, is corrected and slightly enlarged.

Section 2, Electric, Magnetic and Dielectric Circuits, is greatly enlarged. The general theory of electric and magnetic circuits is entirely rewritten and the calculation of inductance and capacity is given in greater detail than before.

Section 3, Measurements and Measuring Instruments, is greatly enlarged. Several new instruments are described, tests of self and mutual inductance have been added and a section devoted to pyrometers and high temperature measurements has been included. The design of rheostats and motor starters has been transferred to Section 5.

Section 4, Properties of Conductor, Resistor and Insulating Materials, is enlarged more than any other section. Many tables have been added giving data on the latest types of conductors and cables. An entirely new section giving the properties of a large number of commercial resistor alloys has also been added and the magnetic testing of iron has been entirely rewritten and now forms a very comprehensive treatment of the latest practice in this important subject.

Digitized by Google

Section 5, Magnets, Resistors, Condensers and Reactors, has been enlarged in scope to include resistors, condensers and reactors. In the sections on magnets, a discussion of the energy relations in a plunger magnet has been added. The section on resistors contains the design of rheostats, formerly in Section 3. To this section have been added the design of induction motor starters, the heating of wires, cables and embedded conductors, the calculation of fuses and tables for use in heating calculations. A new skin effect for various metals has also been added. In the condenser and reactor sections, the electrical calculations are given, and considerable space is devoted to the electrolytic condenser. Almost all of the material in this section is entirely new.

Section 6, Transformers and Converters, is thoroughly revised and considerably enlarged. The use of silicon steel has revolutionized transformer design and hence this section has been completely overhauled. As the book goes to press it is the only available up-to-date treatment of transformers. In the converter section numerous additions are made, the most important being a discussion of the split-pole converter.

Section 7, Generators, has been corrected and slightly revised.

Section 8, Motors, has been revised, discussions of new motors being added to the alternating current commutating motor section. New design data are given for both a.c. and d.c. motors.

Section 9, Batteries, has been corrected and revised, with slight additions.

Section 10, Central Stations, has been thoroughly revised and largely rewritten. The scope is the same. Many cost data have been added.

Section 11, Transmission and Distribution, excepting the underground construction and mechanical transmission, has been entirely rewritten. It is believed now to be thoroughly abreast of the times in the calculation and construction of transmission and distribution systems. Many tables have been calculated especially for this section. Practically all of the old tables have been discarded. Inductive reactance and charging current for all sizes of wire and cable and all spacings are given for 25 and 60 cycles. Tables giving the stresses in wires and cables of various sizes for wind, and wind and sleet conditions are also among the additions.

Section 12, Illumination, has been corrected and revised.

Digitized by Google

Section 13, Traction, has been corrected, revised and enlarged. The locomotive section has been entirely rewritten, and more space has been given to the method of constructing speed-time curves.

Section 14, Electrochemistry, has been thoroughly revised and somewhat enlarged.

Section 15, Telephony, has been entirely rewritten. It is now a comprehensive treatise and represents a new method of presenting the subject.

Section 16, Telegraphy, is corrected.

Section 17, Miscellaneous Applications of Electricity, is corrected and somewhat enlarged.

Section 18, Wiring, is corrected and brought to date.

Section 19, Standards, is considerably enlarged. The latest changes in the A. I. E. E. Standardization Rules have been noted, and standard specifications for rubber insulation, copper conductors and transformers have been added.

Section 20, Tables and Statistics, has been corrected and enlarged by adding telephone, telegraph and central station statistics and by general revision.

Digitized by Google

# PREFACE TO THE FIRST EDITION

In the preparation of the STANDARD HANDBOOK the publishers have adapted the "unit" system to bookmaking. The entire field of electrical engineering was divided into twenty sections or units, each complete in itself. These twenty sections were arranged in what seemed to be a logical order and each was assigned to a specialist. Each author was supplied with a detailed outline of all the sections, thus avoiding repetitions and duplication of material as far as desirable. All of the material thus brought together was carefully edited to obtain uniformity of style, symbols, abbreviations, units, etc., and to connect the various parts by cross-references.

Some repetitions are purposely made to save the time of the user. For instance, transformer oil is treated under Insulating Materials in Section 4, but a brief outline of its important qualities is again given in Section 6 under Transformers, with a cross-reference to guide the reader to the fuller treatment in Section 4.

The Index embodies some new features. All references are made to section and paragraph. In each section the paragraphs are numbered from one to the end, and the section and paragraph numbers are set at the head of the page; the page number appearing in an inconspicuous place at the foot, for the guidance of the printer only. Cross-references are always made through the index to avoid errors and to guide the user to *all* other parts of the book where that subject may be treated.

The studied use of **bold-face type** is also intended to save time by bringing out in a prominent way the real subject of each paragraph.

Recognized standards have been followed wherever possible. Those recommended by the national societies or organizations have usually been followed. Section 19 is entirely given up to Standardization Rules and Reports, including the full report of the American Institute of Electrical Engineers of June, 1907, and that of the American Street and Interurban Railway Engineering Association, ratified in October, 1907.

The publishers cannot hope for absolute accuracy in this

Digitized by Google

first edition of a work containing such a mass of figures and data, although the greatest care has been exercised in its preparation. Any suggestions, criticisms, or corrections from users will be of great service in making THE STANDARD HANDBOOK a standard in fact as well as in name.

*December* 12, 1907.

---

# PREFACE TO THE SECOND EDITION

No new material has been added to this edition of the STANDARD HANDBOOK, with the exception of directions for resuscitation from electric shock, which have been inserted at the end of the book. However, every page has been most carefully read and every possible effort made to insure the accuracy of all data and perfection of the typographical work. Several of the tables, which were especially prepared for this book, have been recalculated and others have been checked by plotting the values and recalculating those which did not fall on a smooth curve.

The success of the STANDARD HANDBOOK has been phenomenal. The general interest in the work has been manifested by the many letters received from prominent men commending its general character and offering suggestions and criticisms. It has already been adopted for use as a text-book in thirty universities and colleges.

The publishers take this occasion to express their appreciation of its reception by the profession, and to thank those who by their kindness in pointing out typographical and other errors, have materially assisted in the work of correction.

NEW YORK, *May*, 1908.

# SECTIONS AND AUTHORS

SECTION 1

**UNITS, CONVERSION FACTORS AND TABLES. By Arthur E. Kennelly, A.M., Sc.D.**

Systems of Units, Historical Sketch, Evolution of Practical Electromagnetic System of Units, Definitions, Dimensional Formulas, Weights and Measures, Conversion Tables and Mathematical Constants and Tables.

SECTION 2

**ELECTRIC AND MAGNETIC CIRCUITS. By Vladimir Karapetoff**

Electric Potential, Electric Currents, Continuous-current Circuits, Electromagnetic Induction, The Magnetic Circuit, Inductance, Hysteresis, Eddy Currents, The Dielectric Circuit, Transient Currents, Alternating-current Circuits, Complex Waves, Polyphase Systems and Transmission Circuits.

SECTION 3

**MEASUREMENTS AND MEASURING APPARATUS. By F. Malcolm Farmer; George K. Burgess, Sc.D.; Paul D. Foote, A.M.; Reginald J. S. Pigott and William J. Driscoll, S.B.**

Galvanometers, E.M.F. and Current Measurements, Resistance Measurements, Power and Energy Measurements, Curve-drawing Instruments; Measurements of Inductance, Capacity, Wave-form, Frequency, Slip, Torque and Speed; Magnetic Measurements, Thermometry, Pyrometry, Heat Conductivity, Fuel and Gas Analysis; Water, Gas, Air and Steam Meters; Precision of Measurements.

SECTION 4

**PROPERTIES OF MATERIALS. By Frank F. Fowle, S.B.**

Conductor Materials, Wire Gages, Wire Tables, Copper, Aluminum, Copper-clad Steel, Iron and Steel, Bronze, Miscellaneous Metals, Resistor Materials, Carbon and Graphite, Skin Effect; Magnetic Materials, Composition and Properties, Core Losses, Sheet Gages, Commercial Sheets, Magnet Steel; Insulating Materials, Classification, Discussion of Properties, Solid Natural Materials, Vitrified Materials, Fibrous Materials, Molded Compositions, Rubber and Its Derivatives, Varnishes and Compounds, Insulating Oils, Gases; Structural Materials, Cast Iron, Wrought Iron, Steel, Annealing, Hardening, Tempering, Steel Wire and Cable, Non-Ferrous Metals, Concrete, Brick, Stone, Timber, Belting and Rope, Properties of the Elements, Atomic Weights, Densities, Specific Heats, Properties of Water and Air.

SECTION 5

**MAGNETS, INDUCTION COILS, CONDENSERS AND RESISTORS. By Charles R. Underhill and Leonard Kebler**

Permanent Magnets, Electromagnets, General Theory, Tractive Electromagnets, Conditions for Maximum Work, Standard Electromagnets, Portative Electromagnets, Polyphase Electromagnets, Heating, Magnet Wires, Calculations, Construction, Testing; Induction Coils, Types, Windings, Interrupters; Condensers, Types, Plate Condensers, Electrolytic Condensers; Resistors, Field Rheostats, Speed-regulating Rheostats, Dimmers, Starting Rheostats, Battery-charging Rheostats and Resistance Units.

SECTION 6

**TRANSFORMERS AND RECTIFIERS. By Charles Le G. Fortescue**

Theory, Design, Insulation, Cooling, Coil Grouping, Transformers for Power Service and Distribution Systems, Multiple Operation, Polyphase Transformations, Constant-current Transformers, Auto-transformers, Instrument Transformers, Miscellaneous Applications, Testing, Installation, Care and Operation; Potential and Current Regulators, Reactors and Rectifiers.

Digitized by Google

SECTION 7

**ALTERNATING-CURRENT GENERATORS AND MOTORS By Comfort A. Adams and Henry M. Hobart**

Synchronous Machines, Armature Winding, E.M.F. Generation, The Magnetic Circuit, Characteristics of Synchronous Alternators, Synchronous Motors, Parallel Operation, Design, Insulation, Efficiency, Ventilation, Construction and Testing; Induction Machines, Theory of Polyphase Motors, Characteristics, Magnetising Current, Leakage Reactance, Circle Diagram, Efficiency, Standard Polyphase Motors, Induction Generators, Design, Single-phase Motors and Their Speed Control; Commutator Motors, Auxiliary Commutating Machines, Phase Modifiers, Motor-generators and Frequency Changers.

SECTION 8

**DIRECT-CURRENT GENERATORS AND MOTORS. By Alexander Gray, B.Sc., Whit. Sch.**

Types, Windings, Armature Reactions, Commutation, Armature Design, Field Design, Construction, Insulation, Cooling, Efficiency, Characteristics, Regulation, Weights, Costs, Standard Machines, Thury System, Motor-generator Sets, Operation and Testing.

SECTION 9

**CONVERTERS AND DOUBLE-CURRENT GENERATORS. By F. D. Newbury, M.E. and Alexander Gray, B.Sc., Whit. Sch.**

Synchronous Converters, Theory, Design, Characteristics, Applications, Operation, Testing; Inverted Converters, Motor Converters, Direct-current Converters, Dynamotors and Double-current Generators.

SECTION 10

**POWER PLANTS. By Reginald J. S. Pigott, Arthur T. Safford and George I. Rhodes**

Steam Power Plants, Laws of Heat Transfer, Boilers, Furnaces, Stokers, Chimneys, Mechanical Draft, Fuel, Water Supply, Coal and Ash Handling, Engines, Turbines, Condensers, Heaters, Economisers, Pumps, Piping and Testing; Gas Power Plants, Producers, Superheaters, Condensers, Scrubbers, Purifiers, Holders, Properties of Gas, Engines, Piping and Testing; Oil Power Plants, Engines, Testing; Hydraulic Power Plants, Hydraulics, Flow Formulas, Stream Flow, Dams, Headworks, Water Wheels and Testing; Buildings and Foundations; Electrical Equipment, Generators, Excitation, Voltage Control, Switching, Station Transformers, Lightning Arresters and Wiring; Power-plant Economics.

SECTION 11

**POWER TRANSMISSION. By Harry E. Clifford, S.B. and Chester L. Dawes, S.B.**

Transmission Systems, Electrical Calculations, Tables of Reactance and Charging Current, Design, Corona, Insulators, System Connections, Switching, Spans and Supports, Construction, Cables, Substations, Operation, Economics and Cost Data.

SECTION 12

**DISTRIBUTION SYSTEMS. By Harry Barnes Gear, A.B., M.E.**

Classification, Applications, Types of Circuits, Circuit Design, Substations, Regulation, Secondary Distribution, Transformation, Protection, Construction and Economics.

SECTION 13

**INTERIOR WIRING. By Terrell Croft**

Fire Risk, Methods of Wiring, Wires and Cables, Fittings and Accessories, Calculations, Lay-outs, Installation, Protection and Miscellaneous.

Digitized by Google

SECTION 14

**ILLUMINATION. By Preston S. Millar**

Production of Light, Incandescent Lamps, Carbon Filament, Metallised Carbon Filament, Tantalum, Tungsten, Gas-filled Type; Arc Lamp Characteristics, Carbon-electrode, Flame Arc, Metallic Electrode, Tube Lamps, Lighting Accessories, Reflectors, Indirect and Semi-indirect Lighting; Illumination Calculations, Flux, Candle-power, Intensity, Brightness, Efficiency; Applied Illumination, Fundamentals of Vision, Characteristics of Illumination, Physiological and Psychological Effects, Methods, Design, Costs; Photometry, Fundamentals, Standards, Apparatus, Spectrophotometers, Colorimeters and Testing.

SECTION 15

**INDUSTRIAL MOTOR APPLICATIONS. By the following specialists:**

| | | |
|---|---|---|
| Leon P. Alford | Chester W. Drake | Arthur C. Eastwood |
| Wilfred Sykes | David L. Lindquist | Fred J. Postel |
| Joseph H. Brown, Jr. | Merton S. Leonard | C. D. Gilpin |
| H. McL. Harding | Graham Bright | Augustus C. Smith |
| William W. Crosby | Joseph H. Wallace | Charles E. Carpenter |
| John F. Harrison | Wirt S. Scott | Frits Balzer |
| Bernard Lester | Clark T. Henderson | |

Machine Tools, Wood-working Machinery, Traveling Cranes, Electric Hoists, Elevators, Power Pumps, Air Compressors, Fans and Blowers, Coal and Ore Handling Machinery, Telpherage Systems, Steel Mills, Cement Mills, Coal Mining, Refrigerating Plants, Textile Mills, Paper and Pulp Mills, Printing, Binding and Linotype Machinery, Flour Mills, Beet-sugar Mills, Laundry Machinery, Small-motor Applications and Motor Control.

SECTION 16

**ELECTRIC RAILWAYS. By Albert H. Armstrong, Norman W. Storer, Asel Ames and Albert F. Gans.**

Electric Traction, Train Resistance, Speed-time Curves, Motor Characteristics, Energy and Power Consumption, Motor Control, Types of Motors, Braking, Trucks and Car Bodies, Self-propelled Cars, Locomotives, Distribution, Substations, Track Switches; Railway Signalling, Types of Fixed Signals, Trolley-operated Systems, Track Circuits, Interlocking, Block System; Electrolysis, Surveys, Means of Prevention, Municipal and State Regulations.

SECTION 17

**ELECTRIC COMMERCIAL VEHICLES. By Stephen G. Thompson.**

Classification, Chassis Construction, Vehicle Resistance, Energy Consumption, Transmission Gear, Motors, Controllers, Batteries, Instruments, Garage Equipment and Comparative Performance and Economy.

SECTION 18

**ELECTRIC SHIP PROPULSION. By Henry M. Hobart**

Ship Resistance, Propeller Characteristics, Systems of Propeller Drive, Types of Vessel For Different Service, Electric Propulsion and Examples of Electrically Propelled Ships.

SECTION 19

**ELECTROCHEMISTRY. By E. F. Roeber, Ph.D.**

Interpretation of Chemical Equations, Laws of Gases, Laws of Solutions, Energy Relations, Electric Furnaces and Their Products, Electrolytic Processes and Reactions, Industrial Electrolytic Processes, Electroplating, Refining of Metals; Electrolysis of Water, Alkaline Chlorides, Copper, Nickel, Zinc, Aluminum, Sodium, Magnesium and Calcium; Discharges through Gases, Fixation of Atmospheric Nitrogen, Electromagnetic and Electrostatic Processes.

Digitized by Google

SECTION 20

**BATTERIES. By Walter E. Winship, Ph.D.**

Primary Batteries, Wet Cells, Dry Cells, Storage Batteries; Lead Storage Batteries, Electrolyte, Testing, Stationary Batteries, Vehicle Batteries, Train-lighting Batteries, Miscellaneous Applications, Battery Rooms, Regulating Equipment, Operation, Depreciation and Maintenance; Alkaline Storage Batteries.

SECTION 21

**TELEPHONY, TELEGRAPHY AND RADIOTELEGRAPHY. By Frank F. Fowle, S.B., and Louis W. Austin, Ph.D.**

Telephone Instruments, Switchboards, Intercommunicating Systems, Phantom Circuits, Manual Telegraph Systems, Simplex and Composite Sets, Dispatching and Patrol Systems, Fire and Police Alarm Systems, Cables, Protectors, Cross-talk and Inductive Disturbances, Transmission, Construction, Testing; Radiotelegraphy, Antenna, Receiving Circuits, Detectors, Wave Transmission, Undamped Oscillations, Arc-wave Generator, Continuous Oscillations, Wireless Telephones, Directive Antennas and Measuring Instruments.

SECTION 22

**MISCELLANEOUS APPLICATIONS OF ELECTRICITY. By the following specialists:**

| | | |
|---|---|---|
| W. S. Hadaway, Jr. | Otis Allen Kenyon | John C. Bogle |
| Harry B. Gear | H. A. Hornor | Capt. Edw. D. Ardery |
| John E. Newman | Frank F. Fowle | Milton W. Franklin |
| Edwin P. Adams | Ernst J. Berg. | Eugene W. Caldwell, M.D. |

Resuscitation, Electric Heating and Cooking, Electric-Welding, Electrical Equipment for Gas Automobiles, Thawing Water Pipes, Marine Applications, Electricity in the U. S. Army, Electricity and Plant Growth, Windmill Electric Plants, Ozone Production, Radioactivity and the Electron Theory, Roentgen Rays, Lightning Rods, Electrostatic Machines, Electric Piano Players, Telegraphone, Telharmonium, Train-lighting Systems, Statistics of the Electrical Industry, Specifications and Contracts.

SECTION 23

**MECHANICAL SECTION. Compiled from standard authorities.**

Elements of Sections, Beams, Columns, Shafting, Gearing, Chain Drives, Belts, Rope Drives, Pipe and Screw Threads.

SECTION 24

**STANDARDIZATION RULES OF THE AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS. Approved edition of Dec. 1, 1914**

SECTION 25

**GENERAL ENGINEERING ECONOMICS AND CENTRAL STATION ECONOMICS. By Frank F. Fowle, S.B., and James Raley Cravath**

General Engineering Economics, Definitions, Value, Price, Cost, Capital, Rent, Interest, Annual Charges, Depreciation, Social-economic Investigations, Valuation and Rate Making; Central Station Economics, Factors Relating to Utilization of Investment, Factors Relating to Territory Served, Typical Earnings of Companies, Rate Making and Valuation.

# SECTION 1

## UNITS, CONVERSION FACTORS, AND TABLES

### SYSTEMS OF UNITS

**1. Nature of units.** Engineering makes use of physical quantities in the broadest sense of that term, *i.e.*, including mechanical, chemical, physical, thermal and physiological quantities. In order adequately to compare the magnitudes of physical quantities of the same kind, unit magnitudes, or units, are necessary for each kind of physical quantity dealt with.

**2. Classification of units.** The subdivisions and species into which units may be divided are indicated in the scheme shown in Fig. 1, with explanations which follow in Par. 3.

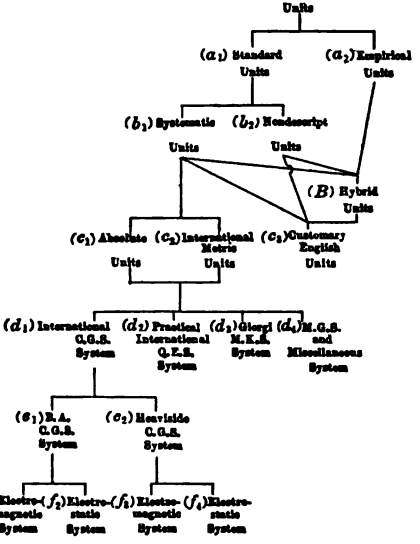

FIG. 1.

**3($a_1$) Standard units** (see Fig. 1) may be said to include all units which have received the stamp of recognition in technical literature.

**3($a_2$) Empirical units,** on the other hand, are units which have sprung into existence locally, ordinarily without any pretense to scientific derivation, and which have not been sanctioned by general usage. At various times during recorded history, empirical units have appeared. Thus, in the early history of electrical units, a unit of conductor resistance was used as representing the resistance of a certain length of a certain size of telegraph

Digitized by Google

wire, as embodied in a certain standard resistance coil. Similarly, the average e.m.f. of a Daniell cell was originally an empirical unit of e.m.f.

3($b_1$) **Systematic units** are units of any definitely related group. Thus the units "pint," "quart," "peck," and "bushel" entering into "dry measure" are systematic units; because they stand in definite quantitative mutual relation as a group or system. Again, the units "mill," "cent," "dime," and "dollar" entering into American currency are systematic units.

3($b_2$) **Nondescript units** may be defined as standard units which are not systematic, or do not enter into any unit system. Thus, in Pennsylvania, a "bushel" of coarse salt, as a weight-unit, is 80 lb. avoirdupois,* but in Illinois it is 50 lb. avoirdupois.

3(B) **Hybrid units,** in contradistinction to systematic units, are units which do not belong to any one system, but which are derived say from a plurality of different systems; from a systematic and a general unit; or from any combination of standard and empirical units. Thus, a "kilogram" may be defined as a unit of weight in the international metric system; while a "square foot" is a unit of area in the customary English system. But the "kilogram-per-square-foot," as a unit of weight loading of floor-area, is a hybrid unit. Occasionally the advantage of practical convenience in the use of a hybrid unit may outweigh the disadvantage of its unsystematic derivation. No stigma necessarily attaches to the use of a hybrid, as distinguished from a systematic unit; but great caution has to be used in pursuing new and unfamiliar quantitative reasoning processes involving hybrid units, lest numerical errors be introduced by neglect of coefficients.

3($c_1$) **Absolute units** are units of physical quantities selected in a comprehensive scientific system based upon three or more fundamental physical properties, such as length, mass, time, energy, specific gravitational force, etc.; so that simple and fundamental quantitative relations may subsist between the members of the system and that each physical quantity may have one and only one unit in the system. The particular basic units from which a system of absolute units is derived are called the **fundamental units** of that system;† while the units so derived are called the **derived units** in correlation thereto. In a **dynamical system,** the **fundamental units** are **three only** and are: a unit of **length,** a unit of **mass,** and a unit of **time.**‡ Consequently, unless otherwise specified, the term "absolute units" is taken as referring to a scientific system based on fundamental units of length, mass, and time. But whereas only one set of fundamental units has come into recognition—the length-mass-time set above mentioned—several species of this set have been used to some extent; namely, the "foot-grain-second" system,§ the "meter-kilogram-second" system, the **"centimeter-gram-second" (C.G.S.)** system, and the **"quadrant-eleventh-gram-second" (Q.E.S.)** system. Only the last two have come into extensive practical use. The C.G.S. system has become the international scientific system, and the Q.E.S. system an international electromagnetic system in electrical engineering. Any complete electromagnetic absolute system involves five fundamental units, two of which may be constants of the ether.

3($c_2$) **Metric units** are units pertaining to the **international metric system.** This system, which was created in France in 1792, was adopted in France in 1840,‖ in Germany in 1872, in Austria in 1876 and so on from one civilized country to another; until at the present date, the only great communities which have not yet adopted the metric system are the British Empire, the United States and the Russian Empire. The advantage of the system is its simplicity. It is a decimal system, using a single fundamental unit of length (the meter) and one of mass (the gram). The **decimal multiples** of these are distinguished by Greek and Latin **prefixes** common to all branches of the system (Par. 102).

---

* "The World Almanac," 1913, New York, p. 81.

† Everett, J. D. "C.G.S. System of Units," Macmillan Co., 1891, p. 15.

‡ Strictly speaking, a dynamical system of absolute units may employ any desired acceleration as unit acceleration, when the unit force acts on unit mass, yet, if the unit of acceleration be the unit of length per unit of time squared as in the C.G.S. system, the system is called an absolute kinetic system.

3($c_0$) **Customary English units** are the units of the English and American measures, viz., length measure, square measure, land measure, cubic measure, cord measure, dry measure, liquid measure, avoirdupois weight, troy weight, apothecaries weight and jeweler's weight. Each of these measures may be regarded as a system. The complete list may be regarded as a congeries of imperfectly connected systems. Empirical and hybrid units are mingled with the rest.

3($d_1$) **C.G.S. units** are the units of that particular system of absolute units which is based on the **international centimeter**, the **international gram** and the **mean solar second**. That is, they are absolute units employing the metric system in a definite way. A reason for the centimeter having been selected in place of the meter as the fundamental unit of length was that the mass of the cubic centimeter of water (at the temperature of unit density) is the gram or unit mass; whereas the mass of a cubic meter of water would be a million grams.

3($d_2$) **Q.E.S. units** are units pertaining to the quadrant-eleventh-gram-second absolute system; *i.e.*, the system in which the unit of length is $10^9$ cm. or 1 theoretical quadrant of the earth as measured from a pole to the equator, the unit of mass is $10^{-11}$ g.,* and the unit of time the mean solar second, or the 1/86,400th part of the annual mean daily period of revolution of the earth with respect to the sun. This is the system to which the international ohm, volt, ampere, joule, watt, coulomb, farad and henry, belong. The system was not intentionally established as a Q.E.S. system; but the ohm having been arbitrarily selected, for convenience of magnitude, as $10^9$ C.G.S. electromagnetic units, and the volt similarly as $10^8$ C.G.S. units, the rest of the system necessarily coincides with the Q.E.S. system; or is such a system as would be produced by the selection of the quadrant, eleventh-gram and second as fundamental units, together with unity for the permeability and unity for the dielectric constant of the ether.

3($d_3$) **Giorgi units** are units in a combined absolute and practical system devised by Prof. G. Giorgi,† in which the fundamental units are: the meter-kilogram-second-international ohm, and the further assumption that the permeability of free ether, instead of being unity as in the C.G.S. magnetic system, is $\mu_0 = 4\pi \times 10^{-7}$ henry/m. On this basis the ohm-volt-ampere series of practical units become also absolute units. The electric inductivity, instead of being unity, as in the C.G.S. electric system, becomes $k_0 = 1/36\pi \times 10^{-9}$ farad/m. No distinction arises in the Giorgi system between electric and magnetic units. The system is also rectified in regard to $4\pi$ factors, or is **"rationalized"** in the Heaviside sense; so that a number of fundamental equations in the system differ from those of the C.G.S. system in regard to such $4\pi$ factors.

3($d_4$) **M.G.S. units, etc.** Units in an absolute system whose fundamental units are the meter-gram-second, the millimeter-milligram-second, the foot-grain second, etc. None of these extraneous absolute systems have come into extensive use.

3($e_1$) **B.A. units** are the units of the C.G.S. system as established by the British Association for the Advancement of Science‡ in 1862. The electrostatic subsystem was established on the basis of the unit quantity of electricity such that it repelled its prototype at a distance of 1 cm. with a force of 1 dyne. The electromagnetic subsystem was similarly established on the basis of the unit magnetic pole such that it repelled its prototype at a distance of 1 cm. with a force of 1 dyne. This procedure led to the anomalous result that every electromagnetic quantity has a unit both in the electrostatic subsystem and in the magnetic subsystem.

3($e_2$) **Heaviside units** are units in that form of the C.G.S. system which was first suggested by Mr. Oliver Heaviside in 1882.§ He showed that if a unit electric point charge and a unit magnetic point pole had been respectively defined such that unit total flux emanated therefrom, the strength of

§ Heaviside, O. "The Relations between Magnetic Force and Electric Current." The Electrician, London, Nov. 18, 1882.

Digitized by Google

the field at unit distance would be $1/(4\pi)$, and this, not unity, should be the force in dynes that the prototype would develop in repulsion. As a consequence of this unnatural definition of the B.A. unit charge and pole, the fundamental equations of the B.A. system become interlarded with $4\pi$-factors in rectilinear problems and denuded of them in spherical problems where they should naturally be expected to occur. Mr. Heaviside proposed to rectify the system by changing the fundamental definitions in the manner suggested, and enunciating a new list of units in both the electrostatic and magnetic subsystems; all related to the corresponding B.A. units in simple powers or roots of $4\pi$. He similarly proposed rectifying the practical or Q.E.S. system of units by adopting a new ohm, volt, ampere, etc., all bearing some ratio of simple power or root of $4\pi$ to the corresponding existing values. If Mr. Heaviside's proposals had been formulated and considered prior to international adoption of the ohm-volt-ampere series of units, and legalized standards, they might have been adopted.* At the present time a very few physicists employ Heaviside's "rational" units in theoretical analysis.†

**4. Fundamental principles concerning units in equations.** Many of the equations representing propositions in pure mathematics may be satisfied by quantities of any kind. Thus taking the very simple equation

$$2(a+b) = 2a+2b$$

it is clear that the quantities $a$ and $b$ may be of the same kind or of different kinds, and their respective units may be any whatsoever, without affecting the identity expressed, so long as $a$ and $b$ have respectively the same meanings on the two sides of the equation. When, however, as ordinarily in engineering, physical magnitudes are dealt with in an equation; then three consequences ensue; namely:

(1) *The equation can only be interpreted in terms of some unit of the particular physical quantity dealt with.* This is the unit of the equation.

(2) *The unit employed on each side of the equation must be the same.*‡

(3) *If either side of the equation contains a simple sum of positive or negative terms; then each of these terms must employ the same unit as the equation.*

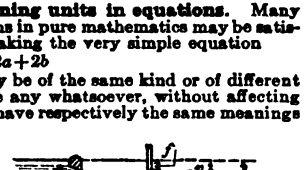

FIG. 2.

For example, considering the case of a uniform pipe, discharging water at a uniform velocity $v$ meters per sec., from a reservoir $A$ into a river $B$ (Fig. 2). Let $H$ be the total head or elevation in meters between the water levels $A$ and $B$ at the two ends of the pipe, and let a vertical pressure pipe be inserted (Fig. 2) at any point $P$. Then we have the well-known hydraulic relation:

$$H = f + \frac{v^2}{2g} + h_1 + h_2 \qquad \text{(meters)} \qquad (1)$$

where $f$ is the loss of head due to friction in the length of pipe $AP$, $g$ is the acceleration due to gravitation in meters per second per second, $v^2/2g$ is the loss of head due to velocity at the point $P$, $h_1$ is the remaining head above the local level, and $h_2$ the height of $P$ above the reservoir level at $B$. Then according to the propositions above stated, each of the four terms on the right hand of the equation must be a head, or height, in meters, and both sides of the equation must be expressed in terms of the same unit. The left-hand term $H$ cannot be in meters and the right-hand terms or any of them in feet or centimeters. The second term on the right hand ($v^2/2g$) contains a velocity $v$, and an acceleration $g$; yet the term as a whole must be a height, if the equation is correct.

The equation might evidently be expressed in terms of any unit of length such as inches, feet, cubits, yards, miles or millimeters. As an algebraic equation entirely by itself, there is no reason for selecting one unit rather

‡ An exception is found in an equation expressing the relation between different units of the same species, as for example, in the equation 1 lb. = 16 oz.

Digitized by Google

than another. The numerical values applying to any particular case covered by the equation will vary greatly according to the unit selected. If, however, any one of the terms is expressed in a particular unit, all the other terms must adopt the same unit. In all cases, however, it is helpful to the reader to have the unit of the equation written out at the end of its line, as above, in order to assist the numerical interpretation.

## HISTORICAL SKETCH OF ENGLISH UNITS

**5. The English weights and measures** are based upon old Roman weights and measures.* The **troy pound** is supposed to have been a weight of silver referred to as a "pound sterling." This pound would be coined into 240 silver pennies or "pennyweights," each of 24 gr. (barley grain weights). It would, therefore, contain 5,760 gr. Heavy bodies (substances in gross outside of coins or bullion) were weighed by "avoirdupois" weight, authorized by law early in the fourteenth century. Several slightly different avoirdupois pounds were in use. Since Queen Elizabeth's reign the avoirdupois pound has been fixed at 7,000 troy grains.

**6. In regard to British lengths,** the earliest seems to have been the **cubit** or half yard. The cubit is a very ancient measure, and corresponds to a forearm length from elbow to middle finger-tip. The royal iron **standard yard** was constructed in the thirteenth century, after which the cubit or **half** yard gradually fell out of use. The **foot** was standardized at one-third of the yard. The mile was a relic of the Roman "millia passuum," or thousand paces; the Roman pace was two of our paces, or counted between the lifts of one and the same foot.

**7. Gallon measures** of volume existed at different times in England in six different forms, such as the corn-gallon, the ale-gallon, etc. Among these, the wine-gallon of Queen Anne contained 231 cu. in. This gallon was brought to America by the early colonists and remains to-day the U. S. gallon. In 1824, the British enacted a new **"imperial gallon"** to supersede all pre-existing gallons, and defined it as the volume of 10 avoirdupois pounds of distilled water at the temperature of 62 deg. fahr. with the barometer at 30 in. It was further defined as a measure containing 277.274 cu. in. of distilled water. There is thus a **difference between British and American gallons** in the ratio 277.274 to 231 = 1.204 : 1; so that the British gallons, quarts, and pints are respectively about 20 per cent. larger than American gallons, quarts and pints, a large discrepancy that has frequently led to misunderstandings.

**8. In land measure,** since Anglo-Saxon times, a **"perch"** or **"pole"** was 11 **cubits** in length = 16½ ft., and such a pole was the **surveyor's unit.** A length of 40 perches was a **furlong,** and 8 furlongs the **statute mile.** An **acre** of land was the area of a rectangular strip a furlong in length and 4 perches in breadth, which breadth was known as the **"acre's breadth."** An acre therefore included $40 \times 4 = 160$ sq. perches. Eight such strips end to end made the statute mile, and 80 such strips side by side made a statute mile breadth; so that a **square statute mile** contained 640 acres. Early in the seventeenth century, Prof. Edmund Gunter of Gresham College decimalised acre measure by inventing a 100-link **"chain"** of outstretched length equal to 4 perches or the acre's breadth (66 ft.). The acre thus became 10 sq. chains.

## HISTORICAL SKETCH OF THE INTERNATIONAL METRIC SYSTEM

**9. Prior to 1790,** differences existed between the weights and measures of different Departments of France. Reform in the directions of simplification and unification was promised in a decree of the National Assembly under the sanction of Louis XVI in 1790. The metric system was actually developed under the authority of the French Republic in 1793, in the hands of a committee of scientists and engineers.

**10. The decimal system,** at the base of the metric system, was originally extended to angles and to time, the right angle being divided into 100 grades, each subdivided into 100 min. and again into 100 sec. The day was divided into 10 hr., each subdivided into 100 min. and again into 100 sec. The decimal subdivision of time never came into extended effect, and the decimal subdivision of angles has only been used to a limited extent.

* Watson, Sir C. M. "British Weights and Measures." London, 1910.

Digitized by Google

**11. The meter** was selected as a length equal to the **ten millionth part of the northern quadrant of the earth,** or distance from pole to equator at the meridian of Paris. Later measurements have shown that the international standard meter finally adopted is shorter than the $10^{-7}$ quadrant by 0.02* per cent. The advantage of such a basis for the meter is that by the use of the decimal subdivision of angles; *i.e.*, by the substitution of 100 grades for 90 deg., the kilometer becomes the natural nautical unit of distance, or the hundredth of the grade; just as the English nautical mile is the sixtieth of a degree.

**12. The metric system** is universally used in all European countries, except Great Britain and Russia. The quantitative literature of the scientific world is almost exclusively written in the metric system. To express quantitative relations exclusively in the English units is to conceal their meaning, to a great extent, from all but English-speaking peoples; and also to discredit them scientifically, by implication.

**13. In the United States,** the metric system has been a legally recognized system since July 28, 1866. In 1893, the U. S. Office of Standard Weights and Measures was authorised to derive the yard from the meter† at the ratio 1 yd. = 3600/3937 meter. The customary weights are likewise referred to the kilogram. The customary weights and measures of the United States are thus defined in terms of, and maintained with reference to, the international metric system.

**14. The international metric standards,** *i.e.*, the standard meter bar and the standard kilogram, are maintained at the International Bureau of Weights and Measures at Sèvres, near Paris, France, in a building which has been declared internationally neutral or outside of French territory. Copies or prototypes of these standards are maintained at the various national laboratories and are occasionally intercompared.

## EVOLUTION OF THE PRACTICAL ELECTROMAGNETIC SYSTEM OF UNITS‡

**15. Brief historical outline.** In 1861 a committee of the **B.A.** (British Association for the Advancement of Science) was appointed to consider standards of electrical resistance. The committee decided to adopt a series of electrical units in the C.G.S. absolute system. The unit of resistance in the C.G.S. magnetic system was so small (one-billionth of an ohm) that it was considered unfit for practical use and a unit $10^9$ times greater than the C.G.S. unit was selected as of convenient magnitude. This decimally derived unit was called the ohm after the German scientist Dr. Ohm. Similarly, the C.G.S. magnetic unit of electromotive force was regarded as unfit for recommendation, and a unit $10^8$ times greater than the C.G.S. unit was selected, and called the volt, after the Italian electrician Volta. The ohm having been selected as a unit, standard resistance coils had to be produced and adjusted—a work of great labor. In 1864 and 1865, certain standards of resistance or **B.A. ohms** were produced and put into service. In 1872, **Mr. Latimer Clark** produced the well-known **zinc-mercury standard cell** which bears his name.

**16. B.A. ohm too small.** In 1878, it was realized that the B.A. ohm was too small by over 1 per cent. That is, the B.A. ohm is now taken to be **0.9866** of the existing **international ohm.**

**17. In 1881 an international electrical congress** at Paris recommended that the standard ohm should be represented as the resistance of a uniform column of mercury, 1 sq. mm. in cross-section, at 0 deg. cent., the length of such a column for the B.A. ohm being approximately 104.9 cm. The Paris Congress of 1881 also adopted the ampere, coulomb and farad, as the practical units of current, quantity and capacity. The practical system based on the ohm and volt thus became virtually the Q.E.S. (quadrant-eleventh-gram-second) system, in place of the C.G.S. system; *i.e.*, as though $10^9$ cm. were substituted for 1 cm. as the unit length, and $10^{-11}$ g. instead of 1 g. as the unit mass.

Digitized by Google

**18. In 1883, an international commission** met at Paris and adopted a length of 106 cm. as the length of the mercury column defining the ohm, as a closer approximation to the true ohm than the B.A. ohm. This 106-cm. ohm was called the "**legal**" **ohm**, as distinguished from the B.A. ohm. Legal ohms, volts, etc., have at the present date almost completely disappeared. They represented an intermediate stage of approximation to the present international unit values.

**19. In 1889, an international electrical congress** at Paris adopted the joule, the watt, and the quadrant, as the practical units of energy, power and inductance, respectively.

**20. Edinburgh conference.** In 1892, a conference was held in connection with the B.A. meeting at Edinburgh. It was then decided to adopt 106.3 cm. as the length of mercury column whose resistance should embody the ohm.

**21. In 1893, the international electrical congress** of Chicago adopted the 106.3-cm. ohm, which was called the **international ohm.** The other units of the practical system adjusted in conformity to this value were called correspondingly the **international ampere, volt, coulomb,** etc. The name of the unit of inductance was changed from the quadrant to the **henry,** in honor of the American physicist of that name.

**22. In 1900, an international electrical congress** at Paris, after some debate, adopted the **maxwell** as the unit of magnetic flux and the **gauss** as the unit either of magnetic intensity or of flux-density in the C.G.S. magnetic system.

**23. In 1908, an international commission** at London considered the **order of sequence of** resistance, current and voltage **standards,** which had been left indefinite at preceding congresses. It was decided that the **ohm** should be the **first unit,** and the **ampere the second,** as determined by the rate of electrodeposition of silver under specified conditions. The volt was to be determined from the ohm and ampere.

## DEFINITIONS OF FUNDAMENTAL UNITS

**24. Length.** (*L.*) Linear distance between any two points. The unit of length in the metric system is the **meter,** in the C.G.S. system the **centimeter,** in the customary system it is any one of the following:—inch, foot, yard, pole, furlong, statute mile, nautical mile.

The fundamental unit of length of the United States is the international meter, the primary standard of which is deposited at the International Bureau of Weights and Measures near Paris, France. This is a platinum-iridium bar with three fine lines at each end; and the distance between the middle lines of each end when the bar is at the temperature of 0 deg. cent., and is supported at the two neutral points 28.5 cm. each side of the centre is 1 m. by definition. Two copies of this bar (prototype meters) are in the possession of the United States and are deposited at the Bureau of Standards.

The United States yard is defined by the relation

$$1 \text{ yd.} = 3600/3937 \text{ m.}$$

The legal equivalent of the meter for commercial purposes was fixed as 39.37 in. by the law of July 28, 1866, and experience having shown that this value was exact within the error of observation, the United States Office of Standard Weights and Measures was, by executive order in 1893, authorized to derive the yard from the meter by the use of this relation.

**25. Mass.** (*M.*) The quantity of matter in a body is estimated either by its inertia or by its weight. In the metric system, the unit of mass is the **gram,** which was originally defined as the mass of a cubic centimeter of distilled water at 0 deg. cent., although in practice it is taken as the thousandth part of a standard kilogram. In the customary system, the unit is ordinarily any one of the following: avoirdupois grain, ounce, pound, or ton (long or short); occasionally, it is one of the Troy system (ounce, pound). In the use of drugs, it is usually stated in apothecaries weight. The mass of precious stones is commonly estimated in carats.

**26. Time.** (*T.*) The interval elapsing between any two events. In the C.G.S. system, the unit of time is the **mean solar second,** or 86,400th part of the mean solar day. In the customary system, it is either the second, minute, hour, day, week or year of mean solar time.

Digitized by Google

**27. Area.** (*A.*) Space occupied in two dimensions. In the metric system, the unit is primarily the **square meter**; but the square dekameter or are is used in land measure; while square millimeter; square centimeter; and square decimeter are also used. In the customary English system the unit may be the square mil, the square inch, square foot, square yard, square chain or square mile.

**28. Volume.** (*V.*) Space occupied in three dimensions. In the metric system, the unit is primarily the **cubic meter** or **stere**; but the cubic decimeter or **liter** is much used, as well as the cubic centimeter and the cubic millimeter. In the customary English system, the units are the cubic inch, cubic foot, cubic yard, cubic mile.

**29. Density.** (*δ.*) Ratio of mass to the volume it occupies. In the metric system the unit is primarily the gram per cubic meter; but decimal derivatives are more common. In the C.G.S. system, the unit is the **gram per cubic centimeter.**

**30. Force.** (*F.*) That which tends to change the energy existing in a given region of space. In mechanics, force is that which tends to produce change of motion in matter. In the C.G.S. system, the unit is the **dyne**, or that force which after acting on a free gram during 1 sec., creates therein a velocity of 1 cm. per sec. In mechanics, the unit force is the force required to support unit mass against standard gravity; *i.e.*, gravity at the standard locality; the weight, at standard latitude and level, of a gram, a kilogram, a pound, etc., according to the system considered.

**31. The weight** of a body is the **gravitational force** acting upon it. Its standard weight is its weight under standard gravitational force. Its local weight is its weight under local gravitational force. In the C.G.S. system the unit for weight is the **dyne.** It is also expressible in the various systems as the gram weight, kilogram weight, the pound weight, etc.

**Important differences of usage** and terminology frequently exist between text-books on physics and text-books on applied mechanics, in regard to the units of mass and of force. These differences are not essentially connected with English weights and measures, because they exist in the text-books of several European countries where the metric system is exclusively employed. In physics, it is customary to regard the terms gram, milligram, kilogram, pound, etc., as designating a mass in the sense above defined. The force exerted gravitationally on such a unit is called the weight of the unit, and is derived from the product of the mass and the gravitational acceleration constant $g$. Thus in an absolute kinetic system, if a body has a mass of $m$ grams, its local weight or gravitational force $F$ is

$$F = mg \qquad \text{(dynes)} \qquad (2)$$

$g$ being the local gravitational acceleration. If the body is transferred to a place where there is standard gravitational acceleration $g_0$, then:

$$F_0 = mg_0 \qquad \text{(dynes)} \qquad (3)$$

In applied mechanics, it is customary to regard the terms gram, kilogram, pound, etc., as designating a weight or gravitational force in the sense above defined; that is, to say one and the same term, "kilogram" say, is used with a different meaning in the two cases here compared. If a body has a standard weight of $W_0$ grams, then by (3),

$$F_0 = (W_0/g_0)g_0 \text{ (grams standard weight)} \qquad (4)$$

so that in the books on applied mechanics, where a mass has to appear in an equation, it is represented by such a term as $W_0/g_0$. The same is true for any system of units. Thus in (3), if $m$ is a mass expressed in pounds, and $g_0$ is the gravitational constant in customary measure, then we might find in a text-book on physics:

$$F_0 = mg_0 \qquad \text{(poundals)} \qquad (5)$$

whereas in a text-book on applied mechanics (4) would have to be written

$$F_0 = (W_0/g_0)g_0 \text{ (standard pounds weight)} \qquad (6)$$

**The centrifugal force** of a mass $m$ pounds whirling with a peripheral velocity $v$ feet per sec. at a radius of $r$ feet would be, according to (5)

$$F = m\left(\frac{v^2}{r}\right) \qquad (\text{poundals}) \qquad (7)$$

---

[*] Everett. "C.G.S. System of Units." New York, Macmillan Co., 1891, p. 28.

Digitized by Google

a **poundal** being the force which acting on a pound mass for 1 sec., develops in it a velocity of 1 ft. per sec. A pound weight is equal to 32.2 poundals. But if we consider a pound to be a force, represented by a weight $W$,

$$F = \frac{W}{g} \cdot \frac{v^2}{r} \quad . \quad (\text{* pounds force}) \qquad (8)$$

It is evident that there is no difference between the two contrasted modes of presenting the facts, provided that we distinguish carefully between a "**pound-mass**" and a "**pound-force.**" If, however, we use the same word "pound" to do duty in the two cases, contradictory and illogical results may be obtained.

It follows that the terms **gram, kilogram, pound, ton,** etc., are susceptible of either of **two distinct meanings;** namely, a **unit of mass** of matter or a **unit of force** equal to the gravitational force exerted on that mass by the earth. Confusion can be avoided in all cases, however, by using distinguishing terms, as "gram-mass," "gram force," or "gram weight."

**32. Linear velocity** ($v$). Rate of movement along a line, and ordinarily along a straight line; also, time rate of change of space. The unit in the C.G.S. system is the centimeter-per-second, in the metric system the meter-per-second, or per minute or per hour. In the customary system, it would be any of the customary English units of length per second, minute, hour or day, etc. Velocities may be either + or − with respect to a selected point on the line of motion.

**33. Linear acceleration** ($a$). Time rate of change of linear velocity. The C.G.S. unit is the (**cm. per sec.**) **per sec.**; or the cm. per sec.$^2$. The metric unit may be a meter per sec.$^2$, or a meter per hour$^2$, or any decimal derivative of the meter, per square of the second, minute, hour, etc. A useful hybrid unit is the (kilometer per hour) per second. Accelerations may be either + or −.

**34. Plane angle** ($\alpha, \beta, \gamma$). In plane circular trigonometry, the ratio of a circular arc to its radius. The C.G.S. unit is the **radian,** or 1 cm. of arc drawn with a radius of 1 cm. The metric unit is the **grade** or one-hundredth of the quadrant with unit radius. The customary unit is either the degree—one-ninetieth of the unit-radius quadrant—or the revolution of four quadrants.

**35. Angular velocity** ($\omega$). In plane circular trigonometry, the time rate of change of angle at any given instant. The C.G.S. unit is the **radian per second.** The customary unit is either the degree per second, or the revolution per second, or per minute, etc. Angular velocities may be either + or −.

**36. Angular acceleration.** In plane circular trigonometry, the time rate of change of angular velocity. The C.G.S. unit is the **radian per second per second.** Customary units are the degree per sec.$^2$, the revolution per sec.$^2$, or per min.$^2$, etc.

**37. Energy** (**W**). The capacity of doing work. Energy may be considered as the fundamental entity in terms of which all dynamical quantities may be defined. In the C.G.S. system, the unit is the **erg, or dyne-centimeter.** In mechanics, it may be any product of a unit weight and unit distance such as kilogram-meter, foot-pound, etc., according to the system. An industrial unit in the meter-kilogram-second system is the **watt-hour.**

**38. Power** (**P**). Activity or the rate of working. The rate of expending energy. The C.G.S. unit is the **erg per second.** The metric gravitational unit is the gram-meter per second, or a decimal derivative, such as the kilogram-meter per second. The absolute unit in the meter-kilogram-second system is the **watt.** The customary unit is the **foot-pound per second,** or the **horse-power** of 550 ft.-lb. per sec. It may be either local or standard.

**39. Momentum.** The product of the mass of a body and its velocity. The C.G.S. unit is the **gram-centimeter per second.** A customary unit is the pound-mass × (foot per second).

**40. Torque** ($\tau$). Twisting effort. The moment of a twisting couple ordinarily exerted about a shaft axis. The C.G.S. unit is the **dyne-perpendicular-centimeter;** *i.e.*, a dyne acting at right angles to a radius arm 1 cm.

* Prof. W. J. M. Rankine. "Applied Mechanics," 9th edition, 1877, page 491.

Digitized by Google

in length. The customary unit is the **pound-weight perpendicular foot.** If the word "perpendicular" is omitted from the unit, care must be taken to distinguish from a dyne-centimeter or a foot-pound weight, which are units of work or energy. A torque is not a work, and can do no work until it advances through an angle.

**41. Pressure (p).** A force integral, or summation of a force, over a surface. A pressure may be either total or specific. A **total pressure,** as its name suggests, is the force integral or **total force** with reference to some particular direction or set of directions. A **specific pressure,** or intensity of pressure, is the ratio of a pressure to the surface area over which it is applied, or the **pressure per unit area.** Unless otherwise specified, a pressure is ordinarily understood to be a specific pressure. The C.G.S. unit of pressure is the **dyne per square centimeter,** sometimes called a "**bar.**"* The metric gravitation unit is the **gram weight per square meter,** or some decimal derivative, such as the kilogram weight per square millimeter. **The standard atmospheric pressure** of 760 mm. mercury at sea-level and 0 deg. cent. at latitude 45 deg., is $1.01321 \times 10^6$ bars or 1.01321 megabar.† Pressures are thus frequently reckoned in atmospheres. They are also frequently expressed as heights of a column of uniform liquid.

**42. Strain.** A change in the shape or size of a body due to the application of a force or set of forces. In the simplest cases, strains are (1) voluminal compressions or dilations; (2) extensions or compressions in one direction with corresponding lateral compressions or dilations (such an extension is called an **elongation**); (3) a twist or shear. These various strains, when small, are expressed as small numerical fractions, in which the numerator expresses the distortion and the denominator the original undistorted value. These strains are ordinarily independent of the system of units employed.

**43. Stress.** The force or set of forces applied to a body, and which tend to produce a strain. They may be either simple forces, pressure intensities, twists, or combinations of the foregoing, and are expressible in the corresponding units.

**44. Young's modulus of elasticity.** The specific tension which would have to be applied to a uniform prism of a substance in order to double its original length, as judged from a small extension under a measured tension. It is a specific tension or longitudinal force per unit area of prism. The C.G.S. unit is the **dyne per square centimeter.** The metric gravitation unit is the gram-weight per square meter or some decimal derivative. A customary unit is the **pound-weight per square inch.**

**45. Moment of inertia of a body with respect to an axis (J).** The product of the mass of the body and the square of its radius of gyration with respect to the axis considered. It is therefore the product of a mass and a distance squared. The C.G.S. unit is the **g-cm.²** The metric unit is a gram-mass-meter.‡ A customary unit is the **pound-mass-foot.**‡ The **radius of gyration** of a body with respect to an axis is the square root of the mean square of the distances of all the particles of the body from the axis. It is therefore a length. The C.G.S. unit is the centimeter. A metric unit is the meter, or decimal derivative. A customary unit is the foot.

## DEFINITIONS OF ELECTRIC AND MAGNETIC UNITS

**46. Electric quantity (Q).** The amount of electricity present in any electric charge or passed through a circuit during any time interval by an electric current. The practical unit is the coulomb, the C.G.S. units are the abcoulomb and statcoulomb.

**47. Electric e.m.f. or pressure (E).** That which tends to make an electric current flow. E.m.f. is ordinarily accompanied by a difference of electric potential; but an e.m.f. may occur without difference of potential, as for example, when a straight bar magnet is thrust symmetrically into a circular loop of uniform wire. A brief current will thus be set up in the wire due to an e.m.f. induced by the magnet's motion; but there will be no difference of electric potential in or around the wire. The practical unit is the **volt.** The C.G.S. units are the abvolt and statvolt.

* Richards and Stull. Carnegie Institution Publication No. 7, p. 43, Dec., 1903.

† Gauthier-Villars. "Les Récents Progrès du Système Metrique." Paris, 1907, pp. 20–31.

Digitized by Google

E.m.f. may be reckoned for a complete circuit or for any portion thereof; that is, each and every portion of a closed circuit in the steady state obeys Ohm's law.

**48. Potential difference (U or V).** A condition in virtue of which an electric current tends to flow from a place of higher to a place of lower potential. The numerical measure of the potential difference is the work done on a unit quantity of electricity in passing between the two points. The practical unit is the **volt.** The C.G.S. units are the abvolt and statvolt.

**49. Potential gradient.** The space rate of change of potential, or the change with respect to distance. An electric potential gradient is the space rate of change of electric potential, and similarly for magnetic, thermal or gravitational potential. The systematic unit in the practical system is the **volt per quadrant,** but a hybrid unit such as **volt per centimeter** is generally used. The C.G.S. unit is either the **abvolt or statvolt per cm.**

**50. Electric current (I).** The rate at which electricity flows through a conductor or circuit. The practical unit is the **ampere,** which is a current of one coulomb per second. The C.G.S. unit is either the **absampere or statampere.**

**51. Electric current density.** The ratio of the current flowing through a conductor to the cross-sectional area of that conductor. More strictly, the current density at a point in a conductor is the ratio of the current through a very small plane element of section containing the point and perpendicular to the current, to the area of the element. The systematic practical unit is the **ampere per square quadrant.** In practice, a hybrid unit is preferred such as the **ampere per square centimeter** or square inch. The C.G.S. unit is either the absampere or statampere per square centimeter.

**52. Electric resistance (R).** Obstruction to electric flow. The ratio of voltage to current in a conductor or closed circuit. The practical unit is the **ohm.** The C.G.S. unit is either the **absohm or statohm.**

**53. Electric resistivity ($\rho$).** The ratio of potential gradient in a conductor to the current density thereby produced. Also the specific resistance of a substance numerically equal to the resistance offered by a unit cube of the substance as measured between a pair of opposed parallel faces. The systematic practical unit is the **ohm-quadrant** or numerically equal to the resistance in a cubic earth-quadrant. A hybrid unit such as the **ohm-cm.** is usually preferred. The C.G.S. magnetic unit is the absohm-cm.

**54. Electric conductance (G).** The conducting power of a conductor or circuit for electricity. The inverse or reciprocal of electric resistance. The practical unit is the **mho.** The C.G.S. unit is either the **abmho** or the **statmho.**

**55. Electric conductivity ($\gamma$).** The specific electric conducting power of a substance. The reciprocal of resistivity. The systematic practical unit is the **mho per quadrant.** A hybrid unit, such as the **mho per cm.** is usually preferred. The C.G.S. magnetic unit is the **abmho per cm.**

**56. Inductance (L).** The capacity for electromagnetic induction possessed by an active circuit either on itself or on neighboring circuits. The ratio of the magnetic flux linked with and due to an active conductor (number of turns $\times$ total flux) to the current strength carried. The practical unit is the **henry.** The C.G.S. units are the **abhenry** and **stathenry.** The term "inductance" seems to have been first introduced by Heaviside* as a brief equivalent for "coefficient of self-induction." Inductance may be divided into two species; namely, **self-inductance** and **mutual inductance.** The unit is the same for both species.

**57. Electric capacity (C).** Sometimes called **permittance** or **capacitance.** The power of storing or holding an electric charge. The ratio of an electric charge on a conductor to the electric potential difference producing the charge. The practical unit is the **farad.** The C.G.S. unit is either the **abfarad** or the **statfarad.** The term "permittance" was introduced by Heaviside.† It should be noted that capacitance is used by a few writers as synonymous with capacity-reactance.

Digitized by Google

**58. Permittivity** is the specific permittance of a substance and numerically equal to the permittance offered by a unit cube of the material as measured between a pair of opposed parallel faces. In the C.G.S. electric system it is equal to $k$, the dielectric constant. Analogous to electric conductivity and magnetic permeability. A term introduced and defined by Heaviside.†

**59. Dielectric constant or specific inductive capacity ($k$).** The ratio of the capacity of a condenser whose coatings are separated by a given substance, to the capacity of a similar condenser whose plates are separated by a vacuum. A pure numeric in any system of units.

**60. Elastance.** The reciprocal of the capacity of a condenser or dielectric. No unit for elastance has been agreed upon in any system. The term "**daraf**" has, however, been suggested for this unit in the practical system, so that a condenser having a capacity of one farad would also have an elastance of one daraf.

**61. Elastivity.** The specific elastance of a substance, and numerically equal to the elastance offered by a unit cube of the substance as measured between a pair of opposed parallel faces. In the C.G.S. electric system it is the reciprocal of permittivity. Analogous to electric resistivity.

**62. Frequency (f).** In a simple alternating-current circuit the number of cycles executed by the current per second. The unit is the **cycle per second.**

**63. Angular velocity ($\omega$)** of a simple alternating-current circuit. The product of the numeric $2\pi$ and the frequency $f$ of the current in cycles per second. The unit employed is the **radian per second.**

**64. Reactance (X).** In a simple alternating-current circuit, the reactive component of the impedance, as distinguished from the active component, resistance. Reactance may be divided into two species of mutually opposite signs; namely, **inductive reactance** or that species of reactance developed in an inductance, $2\pi fL$, and **condensive reactance,** or that species of reactance developed in a condenser, $1/2\pi fc$. Inductive reactance is denoted (when using the method of complex imaginary quantities) by the sign $+j$ or $+\sqrt{-1}$, and condensive reactance by the sign $-j$ or $-\sqrt{-1}$. The unit of reactance in the practical system is the **ohm.** The C.G.S. unit is either the absohm or statohm.

**65. Impedance (Z).** The apparent resistance of an alternating-current circuit or path. The **vector sum** of the **resistance** and **reactance** of the path. The practical unit is the **ohm.** The C.G.S. unit is either the absohm or statohm.

**66. Admittance (Y).** The reciprocal of the impedance of an alternating-current circuit or path. A plane vector or complex quantity.

**67. Conductance (G).** In a direct-current circuit, the reciprocal of the resistance. The practical unit is the **mho.** In Germany it is called the **Siemens.** The C.G.S. unit is either the abmho or the statmho.

In a simple alternating-current circuit, the conductance is the active component of the admittance, or the quantity which multiplied by the root-mean-square impressed alternating voltage gives the active component of root-mean-square current, or the component in phase with the e.m.f. The practical unit is the mho. The C.G.S. unit may be either the abmho or statmho.

**68. Susceptance (B).** The reactive component of admittance in a simple alternating-current circuit. The practical unit is the **mho.** The C.G.S. unit may be either the abmho or statmho.

**69. Magnetic poles.** Those portions of the surface of a magnetic source where the magnetic flux enters or leaves the surface. Magnetic poles appear wherever there is an abrupt change of permeability.

**70. Magnetic pole strength.** The total flux entering or leaving a pole divided by $4\pi$. No name has been provided for this unit. The product of magnetic pole strength and the length of the magnet (interpolar distance) is the **magnetic moment.**

**71. Magnetic flux ($\phi$).** The magnetic flow or current that passes through any magnetic circuit. The C.G.S. magnetic unit is the **maxwell.**

† Heaviside, O. "Electrical Papers." 1892, Vol. II, p. 329.

Digitized by Google

**72. Magnetic flux-density** (ℬ). The ratio of the magnetic flux in any cross-sectional element of a magnetic circuit to the area of that element. The C.G.S. magnetic unit is the **gauss**, which is also a maxwell per square centimeter.

**73. Magnetomotive force** (m.m.f.). That which produces magnetic flux. The analogue in the magnetic circuit of electromotive force in the electric circuit. No name has been provided for the unit of m.m.f. either in the practical or in the C.G.S. magnetic system. The name of **gilbert** has, however, been suggested for the latter. A convenient practical unit is the **ampere-turn** which is $4\pi/10$ gilberts.

**74. Magnetic field intensity** ($\mathcal{H}$) or **gradient of magnetic potential**, also termed **magnetizing force**. The rate of change of magnetic potential with respect to distance. In a region of unit permeability, the field intensity is numerically equal to the magnetic flux density. The provisional name of the C.G.S. magnetic unit is the **gilbert per centimeter**. A numerically related hybrid unit is the **ampere-turn per centimeter**.

**75. Reluctance** (ℜ). Obstruction to magnetic flow. In a simple magnetic circuit, the ratio of the m.m.f. to the magnetic flux. A provisional name for the C.G.S. magnetic unit is the **oersted**. One gilbert m.m.f. acting on a magnetic circuit of one oersted reluctance produces one maxwell of flux.

**76. Reluctivity** ($\nu$). A specific reluctance, numerically equal to the reluctance of unit cube of a substance between any pair of opposed parallel faces. The C.G.S. magnetic unit is the **oersted-cm.**

**77. Permeance.** The reciprocal of reluctance. Conducting power for magnetic flux. No name has been adopted for this unit.

**78. Permeability** ($\mu$). The reciprocal of reluctivity, or **specific permeance.** No name has been adopted for this unit. In the dimensional formulas of the C.G.S. system, if the electric and magnetic constants of the æther are considered as mere numerics; both permeability and reluctivity are also mere numerics. Also magnetic intensity has the same dimensions as flux density;* so that on this basis, which was at one time undisputed, there would be no difference between gilberts-per-centimeter and gausses except numerically. It is now generally admitted,† however, that the electric and magnetic constants of the æther should not be taken as mere numerics; although their dimensional formulas are not defined. On the latter basis, there is a dimensional difference of some kind between magnetic intensity in gilberts-per-centimeter and flux-density in gausses. The permeability can also be expressed $\mu = 1 + 4\pi\kappa$ where $\kappa$ is the **susceptibility**.

**79. Names for the units in the C.G.S. magnetic and electric subsystems.** Although the practical ohm-volt-ampere series of units is universally employed in the great majority of electrical applications, yet it is sometimes desirable to use the C.G.S. parent system of units and names for such units have only been assigned authoritatively in a few instances, such as the "dyne" for the unit of force, and the erg for the unit of work. It has been suggested‡ that the C.G.S. magnetic units might be distinguished from their prototypes in the practical system by the **prefix ab- or abs-** and also that the C.G.S. electrostatic units might be similarly distinguished by the **prefix abstat- or stat-**, as indicated in the following table, Par. **80**.

It should be borne in mind that the prefixes "ab" and "stat" have never been authorized by any technical society or institution, and terms bearing these prefixes are therefore technically irregular. The excuse for this irregularity is that no proper terms exist by which to describe these units, since the phrases "C.G.S. magnetic unit," or "C.G.S. electric unit," are cumbersome and insufficiently descriptive. Moreover, there can be no ambiguity concerning the meaning of these irregular terms.

## DEFINITIONS OF PHOTOMETRIC UNITS

**81. Luminous flux (F), (light)** is the physical stimulus produced by radiation, which excites vision. It is proportional to the rate of flow of radiant energy and to a **stimulus coefficient** which depends chiefly on the spectral distribution of that energy. The stimulus coefficient for radiation of a particular wave-length is the ratio of the luminous flux to the radiant power producing it. The conventional unit of luminous flux is the **lumen** or the flux emitted by **one international candle** through one **steradian.**

**82. Luminous intensity (I), or candle-power.** The luminous intensity of a point source of light is the solid-angular density of the luminous flux emitted by the source in the direction considered; or it is the flux per steradian in that direction. The conventional unit is the candle-power, or the (candle) lumen per steradian.

**83. International candle.** A standard of luminous intensity, conventionally equal to the **bougie decimal,** maintained between the national laboratories of England, France and America through the medium of groups of standard incandescent lamps seasoned and intercompared. The intensity given by this standard is the conventional unit or candle.

**84. True specific luminous intensity** ($b_s$) of an element of a luminous surface is the ratio of the luminous intensity of the element, taken normally, to the area of the element. The conventional unit is the **candle per square centimeter**; or the lumen per sq. cm.

**85. Apparent specific luminous intensity, or brightness** (b), of an element of a luminous surface, from a given position, is the luminous intensity per unit area of the surface projected on a plane perpendicular to the line of sight, and including only a surface of dimensions small in comparison with the distance from the observer. The conventional unit is the **candle per square centimeter of projected area**; or the apparent lumen per sq. cm. For luminous surfaces obeying Lambert's law, or the "cosine law," the true and the apparent specific luminous intensities are equal. In practice, the apparent specific intensity is ordinarily observed. It has been proposed to call a brightness of one apparent lumen per sq. cm. one "lambert".

**86. Illumination on a surface (E)** is the luminous flux-density over the surface, or the flux per unit of intercepting area. The practical unit is the **lumen per square foot** or the **foot-candle.** The conventional unit is the **lumen per square centimeter** which has been termed the **"phot"** by Blondel. It is a cm-candle. The meter-candle, or $10^{-4}$ phot, is sometimes called the candle-lux. The milliphot ($10^{-3}$ phot = millilumen per square centimeter) is roughly equal to a foot-candle, since 1 foot-candle = 1.0764 milliphots.

## DEFINITIONS OF THERMAL UNITS

**87. Temperature.** The thermal condition of a body considered with reference to its capability to communicate heat to other bodies. Bodies at the same temperature do not communicate heat to one another at their bounding surfaces. The conventional unit is the **degree centigrade.** Other units in practical use are the degree **fahrenheit,** and occasionally the degree **réaumur.**

**88. Quantity of heat.** The amount of heat energy contained in a body or transferred from one body to another, by virtue of which temperatures are established or changed. Since heat is a form of energy, a quantity of heat may be expressed in units of energy of any kind. Two types of units are employed, one thermal, the other dynamical. As thermal units the C.G.S. unit is the **"lesser-calorie"** or **"therm"** or **"water-gram-degree centigrade,"** *i.e.*, the quantity of heat required to raise 1 g. of water 1 deg. cent.; and as this differs slightly with the temperature, the interval from 15 deg. to 16 deg. cent. is given in the definition. A larger decimal multiple of this unit, called the **"greater calorie"** or **"kilogram-calorie"** is much used and is equal to 1,000 lesser calories. A practical unit is the **"British thermal unit"** (B.t.u.), or the heat required to raise 1 lb. of water 1 deg. fahr. Dynamic units are the erg, the joule, the watt-hr., etc.

Digitized by Google

**89. Specific heat** is the ratio of the quantity of heat required to raise unit mass of the substance through unit difference of temperature, to that required to raise unit mass of water the same interval. In the C.G.S. thermal system this is numerically the same as the quantity of heat required to raise 1 g. of the substance 1 deg. cent. at the temperature considered. The unit is a mere numeric in any system.

**90. Thermal conductivity.** A specific thermal conducting power. It is numerically equal to the flow of heat occurring through a 1-cm. slab of the material, through a cross-sectional area of 1 sq. cm., when the difference of temperature between the surfaces of the slab is 1 deg. cent. The C.G.S. dynamical unit is the abwatt per centimeter and per degree centigrade.

**91. Thermal resistance.** Opposition to the flow of heat by conduction. Unit thermal resistance in a heat conductor permits unit flow of heat under unit difference of temperature. If the flow of heat is measured in abwatts or ergs per second, and the difference of temperature is in deg. cent., the unit has been called the thermal absohm. If the flow of heat is measured in watts, the unit has been called the thermal ohm.

**92. Thermal resistivity.** The reciprocal of thermal conductivity, and measurable in thermal ohm-cm. or absohm-cm.

**93. Latent heat.** The quantity of heat required to change the physical state of unit mass of a substance without changing its temperature, as for instance to convert 1 g. of water at 100 deg. cent. into saturated dry steam at 100 deg. cent. The dynamical C.G.S. unit is the erg per gram.

**94. Entropy.** A quantitative property of a body which is constant when the quantity of heat contained in it is constant; but which increases or decreases as the body gains or loses heat. In any small change of the quantity of heat contained in the body, the change in entropy is the ratio of the change in quantity of heat to the absolute temperature at which the change took place. The C.G.S. unit is the erg per degree absolute.

**95. Coefficient of expansion,** at any temperature, is the ratio of the change in dimensions of a body to the original dimensions, per degree centigrade of temperature increase. The expansion may be linear, as in the case of a metallic wire; or it may be voluminal as in the case of a fluid. In either case the unit is a numeric divided by a change of temperature.

**96. Emissivity.** The rate of emission of heat from a body per unit of surface area and per degree centigrade elevation of temperature above its surroundings. The C.G.S. dynamical unit is the erg per second, per square centimeter and per degree centigrade.

**97. Mechanical equivalent of heat.** The value in mechanical units of energy corresponding to a given quantity of heat; and, in particular, the value in mechanical units corresponding to a unit quantity of heat such as a lesser calorie or a B.t.u.

## DIMENSIONAL FORMULAS

**98. Each and every derived unit** in an absolute system is necessarily formed from the fundamental units of that system in one and only one combination. The particular combination of fundamental units entering into a derived unit expresses its **dimensions,** and when presented algebraically, is called the **dimensional formula** of the unit. Any statical or dynamical unit in a kinetic absolute system involves only three fundamental units, or has dimensions in three fundamental units. Electric or magnetic units involve five fundamental units.

**99. As a simple example,** we may consider the unit of velocity. A velocity is necessarily a length divided by a time. The notion of mass is not involved in the concept of velocity. Consequently, if we denote the units of length, mass and time by $L$, $M$, and $T$, respectively, the nature of unit velocity $V$ is expressed by the formula

$$V = L/T = LT^{-1} \qquad \text{(velocity unit)} \qquad (9)$$

Digitized by Google

The dimensions of velocity are therefore $LT^{-1}$, or the first positive power of length and the first negative power of time. Since mass does not appear in this dimensional formula we may write the formal dimensions of velocity as $L^1M^0T^{-1}$. The three exponents 1, 0 and $-1$ completely define the nature of velocity in any absolute system whose fundamental units are length, mass and time. Moreover, the dimensional formula of a unit assigns at once the size of a unit when systems employing different fundamental units are compared. Thus if we should compare the unit of velocity in the C.G.S. system with that, say, in the meter-kilogram-day system; then in the latter the unit would be the meter per day while in the former it would be the centimeter per second.

**100. Taking the more complex case of the magnetic unit** of, say, current-density in a system whose fundamental units are those of both the practical and C.G.S. systems; namely, length, mass, time, magnetic æther constant $\mu$, and dielectric æther constant $k$. Then the dimensional formula of current-density is $L^{-\frac{1}{2}}M^{\frac{1}{2}}T^{-1}\mu^{-\frac{1}{2}}$. If now we compare the size of the practical unit with that of the C.G.S. unit the former has a unit length of a quadrant or $10^9$ cm., and a mass unit of $10^{-11}$ g. Consequently, the size of the practical unit is to the size of the C.G.S. unit in the ratio $(10^9)^{-\frac{1}{2}} \times (10^{-11})^{\frac{1}{2}} = 10^{-10}$; so that the practical unit, the ampere per square quadrant, is less than the C.G.S. unit or absampere per square centimeter in the ratio $10^{-10}$. For practical purposes, we should probably ignore the systematic practical unit of current density, the ampere per square quadrant, and select a hybrid unit, say the ampere per square centimeter or per square inch. By such a departure from the absolute system, however, the fundamental equations of the system involving lengths, areas, or volumes, may become erroneous unless we introduce compensating numerical coefficients.

**100a. Vector units and complex quantities.** As is explained in Sec. 2, at Par. **163** and elsewhere, vector alternating quantities are much used in electrical engineering, and call for corresponding vector units, as well as vector symbols, in the formulas relating to such quantities. Strictly speaking, such quantities and units are not vectors in the mathematical sense of that term, but are "complex" quantities and units, because when two such quantities are multiplied together, they do not possess both a "vector product" and a "scalar product" as is the case when two mathematical vectors are multiplied. Nevertheless, such alternating quantities may be called "plane vectors" to avoid conflict with mathematical usage, and the word "vector," which is much used in alternating-current literature, may then be interpreted, in this sense, as subject to the algebra of complex quantities in a plane.

It is not only logical but also very desirable to distinguish between simple and complex quantities, *i.e.*, between scalars and vectors in alternating-current formulas employing both. There are three ways in which this is done:

1. Distinctive symbols, or types of symbol, are used to designate vectors. Thus a scalar e.m.f. in volts might be represented by $E$ and a vector by $\mathfrak{E}$ or $\mathbf{E}$, *i.e.*, by a black letter capital, or by a gothic capital, of the same letter. This method has the disadvantage of calling for and reserving special fonts in representing vectors.

2. The same symbol may be used, but a distinctive mark, such as an "under dot," may be applied to symbols representing vector quantities. Thus a scalar e.m.f. in volts might be represented by $E$, and a vector e.m.f. by $\underset{\cdot}{E}$. In any formula or equation, if any one term is a vector, all of its terms must be vectors; so that the under dot must be applied to each and every term of a vector equation. This method has the disadvantages that it is difficult to print or to set up in type, and that a page containing many vector formulas presents a speckled appearance.

3. No special symbols or symbol marks may be used for vector quantities, but the unit at the end of the line on which the equation appears may have a distinctive sign, such as an angle mark ($\angle$), to indicate that the equation employs vectors. Thus the equation

$$E = IZ_1 + IZ_2 + IZ_3 \qquad \text{volts } \angle$$

would indicate that the e.m.f. $E$ is a vector, and can be represented by the polygonal or vector sum of three vector elements. In this case the unit of the equation becomes a "vector volt."

**101. The international metric system.** There are only three units

Digitized by Google

in the metric system—the meter, the gram and the liter, with decimal derivatives denoted by prefixes common to all parts of the system, including all C.G.S. units and electric or magnetic units.

### 102. The Metric Prefixes

| | | | | |
|---|---|---|---|---|
| Greek roots | Mega- | $= 1{,}000{,}000 = 10^6$ | | Greek for great |
| | Myria- | $= 10{,}000 = 10^4$ | | Greek for 10,000 as in word myriad |
| | Kilo- | $= 1{,}000 = 10^3$ | | Greek for 1,000 |
| | Hecto- | $= 100 = 10^2$ | | Greek for 100 |
| | Deka- | $= 01 = 10^1$ | | Greek for 10 |
| Latin roots | Deci- | $= 1/10$ | $= 10^{-1} = \frac{1}{10}$ | = Latin for 10 as in U. S. dime |
| | Centi- | $= 1/100$ | $= 10^{-2} = \frac{1}{100}$ | = Latin for 100 as in U. S. cent |
| | Milli- | $= 1/1000$ | $= 10^{-3} = \frac{1}{1000}$ | = Latin for 1,000 as in U. S. mill |

Greek Micro- $= 1/1{,}000{,}000 = 10^{-6} = \frac{1}{1{,}000{,}000}$ = Greek for small

**103. Examples of use of prefixes.** The length of 1 statute English mile is expressed in the metric system as 1609.33 meters or 1609.33 m. This may also be expressed as: 1.60933 kilometers or 1.60933 km.

| | |
|---|---|
| or 16.0933 hectometers | or 160933 centimeters |
| " 160.933 dekameters | " 1609330 millimeters |
| " 16093.3 decimeters | " $1.60933 \times 10^9$ microns |

The prefix may be regarded either as designating a secondary unit decimally related to the primary unit, or as indicating a change in the decimal point of the number expressing the dimensions, without changing the unit. Just as the unit of American currency, the dollar, may be expressed either as 1 dollar, 10 dimes, 100 cents, or 1,000 mills, so each of the terms dime, cent, and mill may be regarded either as defining a secondary unit decimally related to the dollar; or as changing the place of the decimal in expressing a sum of money, without departing from the dollar unit; since \$10.93 = 109.3 dimes = 1093 cents = 10,930 mills.

**104. Fig. 3 shows to scale, a length of 1 decimeter,** or about one hand's breadth. This is one-tenth of a meter. It is divided into 10 parts, each 1/100th of a meter or 1 centimeter. Each centimeter is again divided into 10 parts, each 1/1000th of a meter or 1 millimeter.

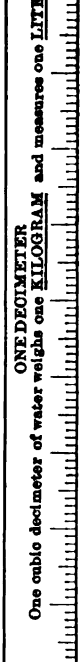

FIG. 3.

**105. If a cube is formed of decimeter edges,** the volume of the cube is a cubic decimeter, and is called a **liter.** It is about midway between a dry U. S. quart and a liquid U. S. quart; so that a liter may be regarded for rough purposes as a quart. One cubic centimeter of water weighs 1 g. So that a liter of water weighs 1,000 g. or a kilogram, which is roughly 2 lb. avoirdupois (2.205 lb.)

**106. Metric length.** 1 meter = 39.37 U. S. inches or roughly a yard or exactly 3 ft. 3 in. $+ \frac{3}{8}$ in. $+ \frac{1}{16}$ in. $+ \frac{1}{125}$ in. Common decimal derivatives are the kilometer (km.) of roughly $\frac{5}{8}$ statute mile; the centimeter (cm.) roughly $\frac{2}{5}$ inch; the millimeter (mm.) roughly $\frac{1}{25}$ inch.

**107. Metric area.** 1 sq. m. = 1.196 sq. yd. or roughly a square yard, and decimal derivatives, such as the square centimeter, or square millimeter. In land measure, a square dekameter or an area 10 m. by 10 m. = 100 sq. m. is called an ar. A square 100 m. by 100 m. = 10,000 sq. m., contains 100 ars or is 1 hectar and forms the metric acre. 1 hectar = 2.471 acres. The square kilometer contains just 100 hectars.

**108. Metric volume.** 1 cu. m., sometimes called a stere, = 1.308 cu. yd. or roughly $1\frac{1}{3}$ cu. yd.

**109. Metric mass.** 1 g. the mass of 1 cu. cm. of water. Common decimal derivatives are the kilogram, or the mass of 1 liter of water; the megagram, or **metric ton,** the mass of 1 cu. m. of water. The metric ton (1,000 kg.) is a little less than the long ton (0.984) so that for many purposes it may be taken as a long ton.

## WEIGHTS AND MEASURES

NOTE:—In this and the following tables, the numerical values are not carried to more than four significant digits, a degree of precision sufficient for ordinary engineering purposes. For higher degrees of precision in conversion factors, reference may be made to publications of the Bureau of Standards, and to Hering's "Conversion Tables."

### 119. Linear Measure*

| English* | U. S. | Abreviation | Metric equivalent | |
|---|---|---|---|---|
| | | | Meter | Reciprocal |
| | 1 mil | | 0.000 0254 | 39,370 |
| 1 inch | 1000 mils = 1 inch | in. | 0.0254 | 39.37 |
| 4 inches = 1 hand | | | 0.1016 | 9.843 |
| 7.92 inches = 1 surveyor's link | 7.92 inches = 1 surveyor's link | | 0.2012 | 4.970 |
| 12 inches = 1 engineer's link = 1 foot | 12 inches = 1 engineer's link = 1 foot | ft. | 0.3048 | 3.281 |
| 3 feet = 1 yard | 3 feet = 1 yard | yd. | 0.9144 | 1.094 |
| 2 yards = 1 fathom | 2 yards = 1 fathom | | 1.829 | 0.5468 |
| 5½ yards = 1 rod, pole, or perch | 5½ yards = 1 rod, pole, or perch | | 5.029 | 0.1988 |
| 100 surveyor's links = 1 surveyor's chain = 66 feet. | 100 surveyor's links = 1 surveyor's chain = 66 feet. | ch. | 20.12 | 0.04970 |
| 100 engineer's links = 1 engineer's chain = 100 feet. | 100 engineer's links = 1 engineer's chain = 100 feet. | ch. | 30.48 | 0.03281 |
| 40 yards = 1 bolt (cloth) | | | 36.58 | 0.02734 |
| 10 surveyor's chains = 1 furlong | 40 rods = 1 furlong | | 201.2 | 0.004970 |
| 8 furlongs = 1 Statute mile | 8 furlongs = 1 mile = 5280 feet | | 1,609 | 0.000 6214 |
| 1.152 statute mile = 1 nautical mile = 1 naut. | 1.152 statute miles = 1 nautical mile = 6080 feet. = 1 naut. | | 1,853 | 0.000 5397 |
| 3 statute miles = 1 league | | | 4,827 | 0.000 2071 |
| 60 nautical miles = 1 degree† | 60 nautical miles = 1 degree† | deg. | 111,100 | $0.9 \times 10^{-5}$ |

* Strictly speaking, there is a small difference between the English and United States inch, foot, yard, etc.; see Hering's "Conversion Tables;" but it is inappreciable for most engineering purposes. The units in the columns marked "English" are taken from Wightman's Arithmetical Tables, London, Old Westminster Press. The units in the columns marked "U. S." are taken from "The World Almanac," N. Y.

† 1 deg. of longitude on the equator is equal, more nearly to 60.07 nautical or 67.17 statute miles (111,300 m.).

### 120. Square Measure

| English | U. S. | Abbreviation | Metric equivalent | |
|---|---|---|---|---|
| | | | Square meters | Reciprocal |
| | 1 circular mil = 0.7854 square mil | | $5.067\times10^{-10}$ | $1.974\times10^{9}$ |
| | 1 square mil | | $6.452\times10^{-10}$ | $1.550\times10^{9}$ |
| | 1 circular inch = 1,000,000 circular mils = 0.7854 square inch. | | 0 000 5067 | $1.974\times10^{3}$ |
| 1 square inch | 1,000,000 square mils = 1 square inch | sq. in. | 0.000 6452 | 1,550 |
| 144 square inches = 1 square foot | 144 square inches = 1 square foot | sq. ft. | 0.09290 | 10.76 |
| 9 square feet = 1 square yard | 9 square feet = 1 square yard | | 0.8361 | 1.196 |
| 30¼ square yards = 1 square rod or perch | 30¼ square yards = 1 square rod or perch | | 25.29 | 0.03954 |
| 40 square rods = 1 rood | | | 1,012 | 0.0009881 |
| 4 roods = 1 acre | 160 square rods = 1 acre | | 4,047 | 0.0002471 |
| 640 acres = 1 square mile | 640 acres = 1 square mile | | $2.590\times10^{6}$ | $3.861\times10^{-7}$ |

### 121. Surveyor's Measure

| English | U. S. | Metric equivalent | |
|---|---|---|---|
| | | Square meters | Reciprocal |
| 1 square surveyor's link | 1 square surveyor's link | 0.04047 | 24.71 |
| 625 square links = 1 square surveyor's pole | 625 square links = 1 square surveyor's pole | 25.29 | 0.03954 |
| 16 square poles = 1 square chain | 16 square poles = 1 square surveyor's chain | 404.7 | 0.002471 |
| 10 square surveyor's chains = 1 acre | 10 square surveyor's chains = 1 acre | 4,047 | 0.0002471 |
| | 40 acres = 1 forty | $1.619\times10^{5}$ | $0.6177\times10^{-5}$ |
| | 4 forties = 1 quarter section | $6.475\times10^{5}$ | $0.1544\times10^{-5}$ |
| 640 acres = 1 square mile | 4 quarter sections = 1 square mile or section | $2.590\times10^{6}$ | $0.3861\times10^{-6}$ |
| | 36 sections = 1 township | $9.324\times10^{7}$ | $0.1073\times10^{-7}$ |

**122. Dry Measure (volume)**

| English | U. S. | Abbreviation | Metric equivalent | |
|---|---|---|---|---|
| | | | Liters* | Reciprocal |
| | 1 pint | pt. | 0.5506 | 1.816 |
| 1 pint | | pt. | 0.5682 | 1.760 |
| | 2 pints = 1 quart | qt. | 1.101 | 0.9081 |
| 2 pints = 1 quart | | qt. | 1.136 | 0.8799 |
| 4 quarts = 1 gallon | | gal. | 4.546 | 0.2200 |
| | 8 quarts = 1 peck | ..... | 8.810 | 0.1135 |
| 2 gallons = 1 peck | | ..... | 9.092 | 0.1100 |
| | 4 pecks = 1 bushel | ..... | 35.24 | 0.02838 |
| 4 pecks = 1 bushel | | ..... | 36.37 | 0.02750 |
| 8 bushels = 1 quarter | | ..... | 290.9 | 0.003438 |
| 36 bushels = 1 chaldron | | ..... | 1309. | 0.0007639 |

* A liter is 1,000 cu. cm.

**123. Cord and Board Measures (volume)**

| English | U. S. | Abbreviation | Metric equivalent | |
|---|---|---|---|---|
| | | | Cubic meters | Reciprocal |
| | 16 cubic ft. = 1 cord foot | cd. ft. | 0.4530 | 2.208 |
| | 8 cord feet = 1 cord* | cd. | 3.624 | 0.2759 |
| | 144 square in. = 1 board foot† | bd. ft. | ..... | ..... |

* A cord is the volume of a rectangular parallelopiped, 8 ft. long, 4 ft. wide, and 4 ft. high = 128 cu. ft.

† The board foot is customarily 144 sq. in. with a thickness of 1 in. Less than 1 in. thick is customarily counted as 1 in.; for example, a board $\frac{7}{8}$ in. or $1\frac{1}{8}$ in. thick would be counted 1 in. thick in board measure.

## CONVERSION TABLES

### 129. Density *

| | Grams per cu. cm. | Reciprocal |
|---|---|---|
| 1 lb. av. per sq. mil. ft. | $2.936 \times 10^{6}$ | $0.3406 \times 10^{-6}$ |
| 1 lb. av. per circular mil-ft. | $2.306 \times 10^{6}$ | $0.4337 \times 10^{-6}$ |
| 1 lb. av. per cu. in. | 27.68 | 0.03613 |
| 1 lb. av. per cu. ft. | 0.01602 | 62.43 |
| 1 grain per cu. in. | 0.003954 | 252.9 |
| 1 lb. av. per cu. yd. | 0.0005933 | 1,685 |

* Tables for converting **deg. Baumé** (liquid density) to specific gravity at 60 deg. Fahr., and vice versa, are given in Circular No. 19, Bureau of Standards, pp. 31–35.

### 130. Time Intervals

| | Mean solar | | | |
|---|---|---|---|---|
| | days | hours | mins. | secs. |
| 1 mean solar year | 365.2 | 8,766 | $5.26 \times 10^{5}$ | $3.156 \times 10^{7}$ |
| 1 week of 7 days | 7.0 | 168 | $1.008 \times 10^{4}$ | $6.048 \times 10^{5}$ |
| 1 mean solar day | 1.0 | 24 | $1.440 \times 10^{3}$ | $8.640 \times 10^{4}$ |
| 1 siderial day | 0.9973 | 23.93 | $1.436 \times 10^{3}$ | $8.616 \times 10^{4}$ |
| 1 mean solar hour | $4.167 \times 10^{-2}$ | 1 | 60 | $3.60 \times 10^{3}$ |
| 1 siderial hour | $4.155 \times 10^{-2}$ | 0.9973 | 59.83 | $3.590 \times 10^{3}$ |
| 1 mean solar minute | $6.944 \times 10^{-4}$ | $1.667 \times 10^{-2}$ | 1 | 60 |

### 131. Solid Angle

| | Sphere | Hemisphere | Spherical right angle | Steradian |
|---|---|---|---|---|
| 1 sphere | 1 | 2 | 8 | 12.57 |
| 1 hemisphere | 0.5 | 1 | 4 | 6.283 |
| 1 spherical right angle | 0.125 | 0.25 | 1 | 1.571 |
| 1 steradian | 0.07958 | 0.1592 | 0.6366 | 1 |

### 132. Force

| | Grams Weight | Reciprocal | Dynes | Reciprocal |
|---|---|---|---|---|
| 1 lb., weight avoird. | 453.6 | 0.002205 | $4.448 \times 10^{5}$ | $0.2248 \times 10^{-5}$ |
| 1 poundal | 14.10 | 0.07092 | $1.383 \times 10^{4}$ | $0.7233 \times 10^{-4}$ |
| 1 grain, weight | 0.06480 | 15.43 | 63.55 | 0.01573 |
| 1 gram, weight | 1 | 1 | 980.665‡ | 0.0010197 |
| 1 short ton, weight | $0.9072 \times 10^{6}$ | $1.102 \times 10^{-6}$ | $0.8896 \times 10^{9}$ | $1.124 \times 10^{-9}$ |
| 1 dyne | 0.0010197 | 980.665‡ | 1 | 1 |

‡ The internationally accepted conventional value of gravitational acceleration at latitude 45 deg. and sea-level. This is usually adopted although later researches have indicated a slightly different value.

## 133. Intensity of Pressure (Force per unit area)

| | Bars or dynes per sq. cm. | Reciprocal | Grams per sq. cm. | Reciprocal | Standard atmospheres of 760 mm. mercury | Reciprocal |
|---|---|---|---|---|---|---|
| 1 Bar, or dyne per sq. cm. | 1 | 1 | $1.0197\times10^{-3}$ | 980.665* | $0.9871\times10^{-6}$ | $1.013\times10^{6}$ |
| 1 Megabar | $10^{6}$ | $10^{-6}$ | $1.0197\times10^{3}$ | $0.9807\times10^{-3}$ | 0.9871 | 1.013 |
| 1 gr. per sq. cm. or 1 cm. water | 980.665* | $1.0197\times10^{-3}$ | 1 | 1 | $0.9680\times10^{-3}$ | $1.033\times10^{3}$ |
| 1 standard atmosphere, 760 mm. mercury at 0° C. | $1.0132\times10^{6}$ | $0.9871\times10^{-6}$ | $1.033\times10^{3}$ | $0.9680\times10^{-3}$ | 1 | 1 |
| 1 lb. avoird. per sq. ft. | 478.8 | $0.2089\times10^{-2}$ | 0.4883 | 2.048 | $0.4726\times10^{-3}$ | $2.116\times10^{3}$ |
| 1 kg. per sq. meter | 98.07 | $1.020\times10^{-4}$ | 0.1 | 10 | $0.9680\times10^{-4}$ | $1.033\times10^{4}$ |
| 1 kg. per hectare | $0.9807\times10^{-2}$ | $1.020\times10^{2}$ | $10^{-5}$ | $10^{5}$ | $0.9680\times10^{-5}$ | $1.033\times10^{5}$ |
| 1 mm. pure mercury | $1.333\times10^{3}$ | $0.7501\times10^{-3}$ | 1.359 | 0.7358 | $1.316\times10^{-3}$ | $0.760\times10^{3}$ |
| 1 in. pure mercury at 0° C. | $3.386\times10^{4}$ | $0.2953\times10^{-4}$ | 34.53 | 0.02896 | 0.03343 | 29.91 |
| 1 lb. avoird. per sq. in. | $0.6894\times10^{4}$ | $1.450\times10^{-5}$ | 70.31 | 0.01422 | 0.06805 | 14.69 |
| 1 long ton per sq. ft. | $1.072\times10^{6}$ | $0.9328\times10^{-6}$ | 1,094 | $0.9141\times10^{-3}$ | 1.058 | 0.9451 |
| 1 short ton per sq. ft. | $0.9574\times10^{6}$ | $1.044\times10^{-6}$ | 976.5 | $1.024\times10^{-3}$ | 0.9451 | 1.058 |
| 1 ft. of water | $2.989\times10^{4}$ | $0.3346\times10^{-4}$ | 30.48 | 0.03281 | $2.950\times10^{-2}$ | 33.90 |
| 1 in. of water | $2.491\times10^{3}$ | $0.4014\times10^{-3}$ | 2.54 | 0.3937 | $2.459\times10^{-3}$ | 406.7 |

* See footnote to preceding table. The sea-level gravitational intensity at any latitude $\phi^{0}$ is expressed by the formula:

$$g_{\phi} = 978.046\,(1+0.005302\sin^{2}\varphi - 0.7\times10^{-5}\sin^{2}2\varphi) \text{ cm. per sec.}^{2}$$
$$= 980.632 - 2.5928\cos 2\varphi + 0.0068\cos^{2}2\varphi \text{ cm. per sec.}^{2}$$

See Annuaire pour l'an 1914, p. 153. For elevations above sea-level, a subtraction of 0.192 cm. per sec.$^{2}$ should be made per kilometer elevation. The range of variation in sea-level gravitation intensity according to the above formula is from 978.05 at the equator to 983.23 at the poles.

* The question is under discussion as to whether a British horse-power should be considered to be 33,000 foot-pounds per min. under the gravitational force of London (g = 981.2), corresponding to 746.0 watts, or under the standard gravitational force conventional for latitude 45° (g = 980.665) corresponding to 745.7 watts, and similarly for the metric horse-power. Both values are therefore offered.

| | Gram per meter | Reciprocal |
|---|---|---|
| 1 lb. per linear yard | 496.1 | 0.002016 |
| 1 lb. per linear foot | 1488 | 0.0006720 |

* A torque is the product of a force and a length taken perpendicularly thereto. Its dimensions are therefore those of force$\times -jL$ where $j=\sqrt{-1}$ or $-jL^2M^1T^{-2}$. Any element of angle is also the ratio of an element of arc length to the length of a radius perpendicular thereto, or has dimensions $jL/L=j$. The product of torque and the angle through which it advances is thus $-jL^2M^1T^{-2}\times j=L^2M^1T^{-2}$ which are the dimensions of work. If the foregoing direction symbols are neglected, a torque appears to have the same dimensions and nature as a work, which is illogical. A torque of 1 g. force acting at a radius of 1 cm. is thus correctly to be expressed as a gram perpendicular centimeter rather than as a gram centimeter.

Digitized by Google

**151. Conversion of Logarithms.** For converting logarithms to the base $a$, to another base $b$:

$$\log_b x = \frac{\log_a x}{\log_a b} \tag{10}$$

$$\log_a b \times \log_b a = 1 \tag{11}$$

**Common or Briggs logarithms** are computed from the base of 10, while **hyperbolic logarithms** are computed from the base $\epsilon$ or 2.7183. Therefore

$$\log_\epsilon x = \frac{\log_{10} x}{\log_{10} \epsilon} \tag{12}$$

**152. The Greek Alphabet**

| Name | Large | Small | Commonly used to designate |
|---|---|---|---|
| alpha | A | $\alpha$ | angles, coefficients. |
| beta | B | $\beta$ | angles, coefficients. |
| gamma | Γ | $\gamma$ | specific gravity. |
| delta | Δ | $\delta$ | density, variation. |
| epsilon | E | $\epsilon$ | base of hyperbolic logarithms. |
| zeta | Z | $\zeta$ | co-ordinates, coefficients. |
| eta | H | $\eta$ | hysteresis (Steinmets) coefficient, efficiency |
| theta | Θ | $\theta$ | angular phase displacement, time constant. |
| iota | I | $\iota$ | |
| kappa | K | $\kappa$ | dielectric constant, susceptibility. |
| lambda | Λ | $\lambda$ | conductivity. |
| mu | M | $\mu$ | permeability. |
| nu | N | $\nu$ | reluctivity. |
| xi | Ξ | $\xi$ | output coefficient. |
| omicron | O | $o$ | |
| pi | Π | $\pi$ | circumference ÷ diameter. |
| rho | P | $\rho$ | resistivity. |
| sigma | Σ | $\sigma$ | (cap.), summation; leakage coefficient. |
| tau | T | $\tau$ | time-phase displacement, time constant. |
| upsilon | Υ | $\upsilon$ | |
| phi | Φ | $\phi$ | flux. |
| chi | X | $\chi$ | |
| psi | Ψ | $\psi$ | angular velocity in time. |
| omega | Ω | $\omega$ | (small), angular velocity in space. |

# SECTION 2

## ELECTRIC AND MAGNETIC CIRCUITS

### ELECTRIC POTENTIAL

**1. The cause of an electric current** in a circuit is termed the **electromotive force** or **voltage.** The latter name is derived from the practical unit of electromotive force called the volt. The current between two points in a circuit is due to a different electric state or "potential" at each point; for this reason the electromotive force or voltage is sometimes called the **difference of potential.**

**2. The electric energy** ($W$) developed or absorbed by an electric circuit may be considered due to the actual flow of an incompressible something which we call electricity. From this point of view, the quantity of electricity $Q$ which is transferred between two points of the circuit is the quantity factor of the energy, while the difference of potential, or the voltage $E$ between the same points, is the intensity factor of the energy ; or

$$W = QE. \tag{1}$$

When $Q$ is in coulombs, and $E$ in volts, $W$ is in joules (watt-seconds). Hence, electromotive force or voltage may also be defined as electrical energy developed or work done per unit quantity of electricity.

**3. Electric Power.**—Dividing both sides of the preceding equation by the time which it takes for the quantity $Q$ to flow through a cross-section of the circuit, we get

$$P = IE, \tag{2}$$

where $P$ is the power, and $I$ the rate of flow or the current. The e.m.f. can thus be defined as the power developed per unit of current.

**4. The principal sources of electromotive force** or difference of potential are the following:

(a) Electromagnetic induction (see Par. 26);
(b) Contact of dissimilar substances (see Par. 5);
(c) Thermo-electric action (see Par. 6);
(d) Chemical action (Sec. 19);
(e) Friction between dissimilar substances (see Sec. 22).

In the light of the modern electrical theory, all these phenonema, with the exception of (a), appear to be but special cases of the general contact action.

**5. In a circuit made up of several substances,** a difference of potential (e.m.f.) exists at each junction of two unlike substances. However, from the law of conservation of energy it follows that unless the circuit contain a source of energy, the resultant e.m.f. in the circuit must be zero and no current can be established. This phenomenon also takes place in circuits made up of a single substance whenever the substance is not physically and chemically homogeneous. The following are the principal cases of thermal and contact action:

(a) **Seebeck effect.** In a closed circuit consisting of two different metals, if the two junctions are kept at different temperatures, a permanent current will flow. Thus, if one junction of a copper-iron circuit be kept in melting ice and the other in boiling water, it will be found that a current passes from copper to iron across the hot junction. If, however, the temperature of the hot junction be raised gradually, the e.m.f. in the circuit slowly reaches a maximum, then sinks to zero, and finally is reversed.

(b) **Peltier effect.** When a current is passed across the junction between two different metals, an evolution or an absorption of heat takes place. This effect is different from the evolution of heat ($i^2r$), due to the resistance of the junction, and is reversible, heat being evolved when the current

Digitized by Google

passes one way across the junction and absorbed when the current passes in the other direction. There is a definite relation between the direction of the thermo-electric current and the sign of the Peltier effect. If a current be forced across a junction in the same direction as the thermo-electric current flows at the hot junction, the junction will be cooled, that is, heat will be absorbed. Conversely, a current passing in the normal direction across the cold junction of a thermo-electric circuit evolves heat. In general, then, a thermo-electric current absorbs heat at the hot junction and gives up heat at the cold junction. Therefore, a current produced in the same direction by external means must cool off the junction which serves as the "hot" junction and warm up the "cold" junction.

(c) **Thomson effect.** In a copper bar, heat is carried with the electric current when it flows from hot regions to cold ones; on the other hand, when the current flows from cold regions to hot ones, these hot parts of the bar are cooled. In iron these effects are reversed. The conductor may be thought of as composed of a number of little elements of volume, at the junctions between which occur reversible heat effects, similar to Peltier effects at the junctions between different metals.

(d) **Volta effect, or contact electrification.** When pieces of various materials are brought in contact, an e.m.f. is developed between them. Thus, in the case of zinc and copper, zinc becomes charged positively and copper negatively. According to the electron theory, different substances possess different tendencies to give up their negatively charged corpuscles. Zinc gives them up very easily; therefore a number of negatively charged particles pass from it to copper. Measurable e.m.fs. are observed even between two pieces of the same substance, having different structures; for instance between a piece of cast copper and electrolytic copper. Frictional electricity is explained in a similar way, only a more intimate contact is necessary where the conductivities of the substances are small.

6. **Literature references.** For a detailed treatment, curves and mathematical theory of thermo-electric and contact phenomena see Maxwell, J. C., "Electricity and Magnetism," Vol. I, Arts. 246 *et seq.*: Encyclopedia Britannica, under "Thermo-electricity"; Whetham, W. C. D., "The Theory of Experimental Electricity," Chap. 6; Brooks and Poyser, "Magnetism and Electricity," Chap. 28. For an explanation of thermo-electric effects in the language of the electron theory see Fournier d'Albee, "The Electron Theory," Chap. 5; Thomson, J. J., "The Corpuscular Theory of Matter," pp. 73 and 97; Campbell, N. R., "Modern Electrical Theory," pp. 118–124.

7. **The value of the e.m.f. at a junction of unlike substances** depends upon the kind of substances, and is approximately proportional to the temperature. The e.m.f. generated in this way can be utilised as a measure of temperature. For temperature rises up to 200 deg. cent.

$$e = k_1 t + k_2 t^2, \tag{3}$$

and for temperature rises above 200 deg. cent.

$$\log e = k_3 \log t + k_4 \tag{4}$$

A more general formula is

$$e = a + bt + ct^2 \tag{5}$$

The quantities $k_1$, $k_2$, $k_3$, $k_4$, $a$, $b$ and $c$ are constants. For numerical values see Sec. 4.

8. **Thermocouples and batteries.** In order to utilize these contact e.m.fs., means must be devised to supply energy to the system continuously. There are two ways of doing this, namely, by heat and by chemical reaction. The thermocouple is an example of the former, and the battery an example of the latter. For further discussion of thermocouples see Sec. 3. Batteries are treated in Sec. 20.

## ELECTRIC CURRENTS

9. **An electric current is defined** as the rate of flow of electricity, or the quantity of electricity which flows through a cross-section of the circuit per unit time. If the current $I$ is steady, then

$$I = \frac{Q}{T} \tag{6}$$

If $Q$ is the quantity of electricity in coulombs, and $T$ the time in seconds,

Digitized by Google

the current $I$ is in amperes. When the rate of flow is non-uniform, the instantaneous current is

$$i = \frac{\partial q}{\partial t}; \qquad (7)$$

for a classification of electric currents see the Standardization Rules of the American Institute of Electrical Engineers, Sec. 24.

**10. Steady and transient states.** An electric circuit may be in a steady or in a transient state. When a current is continuous, or when it varies periodically between the same limits and according to the same law, the circuit is said to be in a steady state. For instance, the circuit of an alternator is steady as long as the load, speed and field excitation are kept constant. The same circuit is in a transient state when the load is switched on or off, or when it is varied in such a way that the same conditions do not repeat themselves periodically. A transient current may be periodic, for instance in a rectifier, in which cycles follow in such rapid succession that the current is very different from the permanent value which it would gradually assume.

**11. A direct current** given out by a chemical battery is constant in value, or **continuous,** when the load is constant. A current delivered under the same conditions by an electric generator or a rectifier is **pulsating,** that is, it varies periodically due to a finite number of commutator segments.

**12. An alternating current** may vary according to the **simple sine law** (Par. **152**), or according to a **more complicated periodic law.** In the latter case the current may be resolved, for purposes of theory and analysis, into a fundamental sine wave, and sine waves of higher frequencies (Par. **209**). Sometimes a complex alternating current or voltage is replaced for practical purposes by an equivalent sine-wave.

**13. Transient currents may be oscillating or non-oscillating,** according to the conditions in the circuit. Oscillations are due to periodic transformations of the electrostatic energy stored in the dielectric into the electromagnetic energy of the magnetic flux linking with the current. During these transformations part of the energy is converted into the Joulean ($i^2r$) heat in the conductors and in surrounding metallic objects, including the iron of the magnetic circuit. Part of the energy is also converted into the heat caused by magnetic and dielectric hysteresis. The oscillations are thus damped out, and their amplitude decreases. When the conditions are particularly favorable for the conversion into heat (high resistance in series, or low resistance in parallel), both the electrostatic and the electromagnetic energy are directly converted into heat, instead of being partly converted into one another. This conversion into heat is an irreversible phenomenon, so that in this case the current is non-oscillating, but gradually reaches its final value. When it is desired to maintain oscillations as long as possible (wireless telegraphy) the series resistance must be kept down as low as possible. When oscillations are harmful (switching in long cables or transmission lines), extra resistance is temporarily connected in the circuit.

**14. Conductors and insulators.** For practical purposes, materials used in electrical engineering are divided into conductors and insulators. A conducting material allows a continuous current to pass through it under the action of a continuous e.m.f. An insulator (more correctly called a **dielectric**) allows only a brief transient current which charges it electrostatically. This charge or displacement of electricity produces a counter-e.m.f. equal and opposite to the applied e.m.f., and the flow of current ceases. The division into conductors and dielectrics is not strictly correct, but convenient for practical purposes. A substance may practically stop the flow of current when the applied voltage is sufficiently low, and at the same time be unsuitable as an insulator at high voltages. Some materials which are practically non-conducting at ordinary temperatures become good conductors when sufficiently heated. For numerical data and tables of conducting and insulating properties of the principal materials used in practice see Sec. 4.

**15. The electronic theory of conduction.** According to the modern electronic or corpuscular theory of electricity, there is an indivisible atom of negative electricity, called the **electron** or the **corpuscle.** Atoms of matter consist of one or more electrons and an unknown something which has the

Digitized by Google

nature of positive electricity. A negatively charged particle of matter is one in which there are more electrons than necessary to neutralize its positive electricity. A positively electrified body is one which has lost some of the electrons it had in the neutral state.

**16. Metals and other solid conductors supposedly possess free or roaming electrons,** in addition to those associated with the molecules. These free electrons are in rapid motion as if they were the particles of a gas dissolved in the metal. When an e.m.f. is applied, each electron gains a component velocity which, on account of its negative charge, is in the opposite direction to the e.m.f. This drift of electrons is equivalent to a current. In their motion the electrons come in collision with the molecules and give up part of their momentum. This loss is supposed to account for the Joulean ($i^2r$) heat set free in all conductors. Also see Sec. 22.

**17. Electrolytes.** In liquids which are chemical compounds (electrolytes) the passage of an electric current is accompanied by a chemical decomposition. Atoms of metals and hydrogen travel through the liquid in the direction of the positive current, while oxygen and acid radicals travel against the positive current. Thus, while in solid conductors electricity travels across the matter, in electrolytes it travels with the matter. For details of electrolytic conduction see Sec. 19.

**18. Gases in the normal state conduct electricity only to a slight degree.** A gas may be put in the conducting state by different means, such as raising its temperature, drawing it from the neighborhood of flames, arcs, or glowing metals, or from a space in which an electric discharge is passing, etc. This conductivity is due to electrons which form electrified particles mixed up with the gas (ions). The process by which a gas is made into a conductor is called the **ionization** of the gas. The movement of free electrons constitutes the current through the gas.* Also see Sec. 19.

## CONTINUOUS-CURRENT CIRCUITS

**19. Ohm's law.** When the current in a conductor is steady and there are no electromotive forces within the conductor, the value of the current $i$ is proportional to the voltage $e$ between the terminals of the conductor, or

$$e = ri \tag{8}$$

where the coefficient of proportionality $r$ is called the **resistance** of the conductor. The same law may be written in the form

$$i = ge \tag{9}$$

where the coefficient of proportionality $g = 1/r$ is called the **conductance** of the conductor. When the current is measured in amperes and the electromotive force in volts, the resistance $r$ is in ohms and the conductance $g$ in mhos.

When there is a **counter-electromotive force $e_c$ within the conductor,** Ohm's law becomes

$$e_t - e_c = ri, \tag{10}$$

or

$$i = g(e_t - e_c), \tag{11}$$

where $e_t$ is the voltage between the terminals of the conductor.

**20. For cylindrical conductors** the resistance is proportional to the length $l$, and inversely proportional to the cross-section $A$, or

$$r = \rho \frac{l}{A}, \tag{12}$$

where the coefficient of proportionality $\rho$ (rho) is called the **resistivity** (or specific resistance) of the material. For numerical values of $\rho$ for various materials see Sec. 4.

The conductance of a cylindrical conductor is

$$g = \lambda \frac{A}{l}, \tag{13}$$

* For the original development of the electronic theory and its application to various electric and magnetic phenomena see numerous books and articles by Sir J. J. Thomson. A popular exposition of the results will be found in Fournier d'Albee's "The Electron Theory" and in a somewhat more advanced "Modern Electrical Theory" by N. R. Campbell.

Digitized by Google

where $\lambda$ (lambda) is called the **conductivity** of the material. Since $g = 1/r$, the relation also holds, that

$$\lambda = \frac{1}{\rho}. \tag{14}$$

For the calculation of resistance of non-cylindrical conductors see the author's "Electric Circuit," Chap. III, and the references given there.

**21. Temperature coefficient.** The resistance of a conductor varies with the temperature according to a rather complicated law. The resistance of all metals and of practically all alloys increases with the temperature. The resistance of carbon and of electrolytes decreases with the temperature. For numerical values see Sec. 4. For many materials the variation of resistance with the temperature can be represented by the relation

$$r_t = r_0(1 + \alpha t) \tag{15}$$

where $r_t$ is the resistance at $t$ deg. cent., $r_0$ the resistance at 0 deg. cent., and $\alpha$ (alpha) is called the temperature coefficient of the material. For numerical values of $\alpha$ for various materials see Sec. 4. When the resistance of a material increases with the temperature, $\alpha$ is positive; otherwise it is negative. For other formulæ see Sec. 4.

**22. Resistances and conductances in series.** When two or more resistances are connected in series the equivalent resistance of the combination is equal to the sum of the resistances of the individual resistors, or

$$r_{eq} = r_1 + r_2 + \text{etc.} \tag{16}$$

When conductances are connected in series, the equivalent conductance $g_{eq}$ is determined from the relation

$$\frac{1}{g_{eq}} = \frac{1}{g_1} + \frac{1}{g_2} + \text{etc.}, \tag{17}$$

in other words, when two or more conductors are connected in series, the reciprocal of the equivalent conductance is equal to the sum of the reciprocals of the individual conductances.

**23. When resistances are connected in parallel,** the equivalent resistance $r_{eq}$ is determined from the relation

$$\frac{1}{r_{eq}} = \frac{1}{r_1} + \frac{1}{r_2} + \text{etc.} \tag{18}$$

or simply

$$g_{eq} = g_1 + g_2 + \text{etc.} \tag{19}$$

**24. The simple rule is: Resistances are added when in series; conductances are added when in parallel.** In the case often met in practice when two resistances are connected in parallel

$$r_{eq} = \frac{r_1 r_2}{r_1 + r_2}. \tag{20}$$

**25. Series-parallel circuits.** In a combination like the one shown in Fig. 1, where some of the resistances are in series, some in parallel, and where it is required to find the equivalent resistance between $A$ and $B$, the problem is solved step by step, by combining the resistances in series, converting them into conductances and adding them with other conductances in parallel. For instance, in the case shown in Fig. 1 begin by combining the resistances $r_2$ and $R$ into one, and determine the corresponding conductance

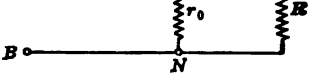

FIG. 1.—Series-parallel circuit.

$$\frac{1}{(R + r_2)};$$

add this conductance to the conductance $1/r_3$. This will give the total conductance between the points $M$ and $N$. The reciprocal of it gives the equivalent resistance between the same points. The total resistance between the points $A$ and $B$ is found by adding $r_1$ to this resistance. When a network of conductors cannot be reduced to a series-parallel combination, the problem is solved as shown in Par. **29.**

Digitized by Google

**26. Power and energy.** When a steady current $i$ flows through a conductor and the voltage across the terminals of the conductor is $e$, the power, or the energy per unit time, delivered to the conductor is

$$P = ei. \tag{21}$$

If the current is expressed in amperes and the potential in volts, the power $P$ is in watts (joules per second). When the voltage and the current are variable, their instantaneous values being represented by $e$ and $i$ respectively, the preceding equation gives the instantaneous power, that is the instantaneous rate at which energy is being delivered to the conductor.

The total energy delivered to the conductor during a time $t$ is

$$W = eit = eQ, \tag{22}$$

where $Q$ is the total quantity of electricity (coulombs) which passed through the conductor. If $Q$ is in coulombs (ampere-seconds), $W$ is in joules (watt-seconds). When the voltage and the current are variable the total energy is expressed by

$$W = \int_{t_1}^{t_2} ei\,dt, \tag{23}$$

where the time interval is $t_2 - t_1$.

**27. Joule's law.** When the conductor contains ohmic resistance only and no counter-electromotive forces, we have $e = ri = i/g$, so that the power

$$P = i^2 r = \frac{i^2}{g} = \frac{e^2}{r} = e^2 g. \tag{24}$$

This expression is known as **Joule's law.**

**28. If the conductor contains a counter-e.m.f., $e_a$,** for instance, that of a motor or of a battery, **the power** is given by

$$P = e_t i = e_a i + i^2 r, \tag{25}$$

where $e_t$ is the voltage across the terminals of the conductor. In this expression $e_a i$ is the useful power, and $i^2 r$ is the heat loss in the conductor. See Par. 19.

**29. Kirchhoff's laws.** In an arbitrary network of conductors (Fig. 2) with sources of continuous e.m.f. connected in one or more places, the distribution of the currents is such that two conditions are satisfied, namely,

$$\Sigma i = 0, \text{ and } \Sigma e = \Sigma ir. \tag{26}$$

The first equation refers to any junction point of three or more conductors and states the fact that as much current flows toward the junction as away from it, because electricity behaves like an incompressible fluid. In this equation all the currents which flow toward the junction are taken with the sign plus (+); all those which flow away from it with the sign minus (−), or *vice versa*. The second law refers to any closed circuit taken at random in the network. The voltages $e$ are the local electromotive forces in such a circuit and the currents and the resistances refer to the individual conductors of the circuit. The directions of flow of the currents can be assumed arbitrarily to start with, and in writing the second equation one follows a selected circuit in a certain direction, clockwise or counter-clockwise, taking as positive the currents which flow in this direction and the e.m.fs. which tend to produce currents in the same direction. The currents and the voltages in the opposite direction are entered in the equation with the sign minus. For a given network of conductors the total number of equations of the first form is equal to the number of junction points less one; the number of equations of the second kind is equal to the number of *independent* closed paths in the network. The total number of equations of both kinds is equal to the number of unknown currents so that these currents can be

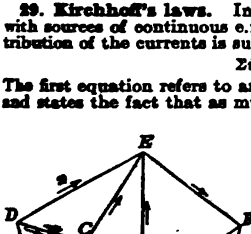

FIG. 2.—Network of conductors.

Digitized by Google

determined by solving simultaneous equations. For an example of such equations see Par. **31** below.

**30. Wheatstone bridge.** The combination of six resistances shown in Fig. 3 is called the Wheatstone bridge. The resistances are denoted by $a, b, c, \alpha, \beta, \gamma$, the currents by $x, y, z, \xi, \eta, \zeta$. An electric battery of e.m.f. $E$ is connected in the branch $BC$, and the value of $a$ includes the internal resistance of the battery. In practice a galvanometer is usually connected in the branch $OA$, and $\alpha$ includes its resistance. When the four resistances $b, c, \beta, \gamma$, are so adjusted that no current flows through $OA$, the bridge is said to be balanced, and the condition holds that,

$$b\beta = c\gamma. \tag{27}$$

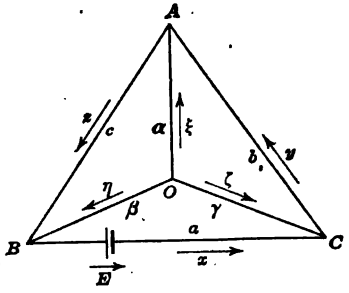

Fig. 3.—Wheatstone Bridge.

**31. Unbalanced bridge.** When the Wheatstone bridge is not balanced, Ohm's law and Kirchhoff's laws give the following equations:

$$\begin{aligned} az &= C - B + E, & \alpha\xi &= A, & \xi + y - z &= 0, \\ by &= A - C, & \beta\eta &= B, & \eta + z - x &= 0, \\ cz &= B - A, & \gamma\zeta &= C, & \zeta + x - y &= 0. \end{aligned} \tag{28}$$

Here $E$ is the battery e.m.f., and $A$, $B$, $C$, denote the potentials of these points below that at $O$. These nine equations contain nine unknown quantities, viz., six currents and three potentials. Solving them as simultaneous equations any of the unknown quantities may be determined. For instance, the current in the galvanometer circuit is

$$\xi = \frac{E}{D}(b\beta - c\gamma), \tag{29}$$

where the "determinant" $D$ is given by

$$D = abc + bc(\beta+\gamma) + ca(\gamma+\alpha) + ab(\alpha+\beta) + (a+b+c)\,(\beta\gamma + \gamma\alpha + \alpha\beta).^*$$

**32. Networks of conductors.** In a general case (Fig. 2) as many Kirchhoff equations (Par. **29**) may be written as there are conductors; the unknown quantities may be the currents, the resistances or the voltages; also any combination of these, provided that the total number of unknown quantities is equal to the number of equations. The equations are conveniently solved by the method of determinants, found in most textbooks on algebra.

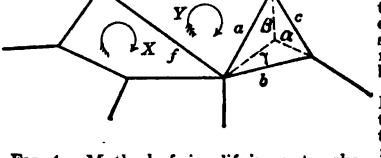

Fig. 4.—Method of simplifying networks.

**33. Maxwell's solution.** In some cases it is convenient to consider, instead of the actual currents, fictitious currents in each mesh (Maxwell, *ibid.*, Art. 282*b*). The actual current in each conductor is equal to the algebraic sum of the fictitious currents. For instance, in Fig. 4 the current in conductor $f$ is the difference of the fictitious currents $X$ and $Y$. The Kirchhoff equations are written for the fictitious currents.

* Maxwell, J. C. "A Treatise on Electricity and Magnetism," Vol. I, Art. 347.

For practical forms of the Wheatstone bridge and its application to the measurement of resistance see Sec. 3.

Digitized by Google

An example of such a solution will be found in Del Mar's "Electric Power Conductors," p. 34.

**34. Equivalent star and mesh (delta).** The number of meshes, and consequently the number of equations, may be reduced, when some of the meshes are in the form of a triangle, like *abc* in Fig. 4. *For the three resistances forming the triangle may be substituted the three resistances* $\alpha$, $\beta$, *and* $\gamma$, *which radiate from one point.*

The currents and the voltages in the rest of the network remain the same, provided that

$$\alpha = \frac{bc}{(a+b+c)}; \qquad \beta = \frac{ca}{(a+b+c)}; \qquad \gamma = \frac{ab}{(a+b+c)}. \tag{30}$$

The number of meshes is thus reduced by one. See Kennelly, A. E., *Electrical World and Engineer*, Vol. XXXIV (1899), p. 413. For a discussion of equivalent star- and delta-connected impedances for alternating currents see his "Application of Hyperbolic Functions to Electrical Engineering Problems," Appendix E.

**35. In the practical case of distributing networks and feeders,** the determination of the currents and voltages at the junction points is simplified by using the following **laws of superposition of currents and voltages.** (1) The true current at any point in the network is the algebraic sum of the currents which would flow if the consumers' currents were taken in succession instead of simultaneously. (2) The voltage drop to any point in the network is equal to the sum of the drops to the same point calculated under the assumption that the consumers' currents are taken in succession, and not simultaneously. Some simplification in the solution of the Kirchhoff equations is possibly due to the fact that the voltage drop along a conductor is usually small as compared to the voltage between it and the return conductor. For details of such calculations see Teichmuller, "Die Elektrischen Leitungen;" F. B. Crocker, "Network of Electrical Conductors," *El. World*, Vol. LIX (1912), pp. 799, 847, 901; Alex. Russell, "The Theory of Electric Cables and Networks," Chap. 4; Nowak, J., "A Machine for the Calculation of Supply Networks," *The Electrician*, Vol. LXVIII (1912), p. 748; Herzog and Feldmann, "The Distribution of Voltage and Current in Closed Conducting Networks," *Trans.* Inst. Elec. Congress, St. Louis, 1904, Vol. II, p. 689; also their book entitled "Die Berechnung Elektrischer Leitungsnetze," and Rziha und Seidener, "Starkstromtechnik," Sec. 8.

## ELECTROMAGNETIC INDUCTION

**36. Faraday's law of induction.** When a magnetic flux $\Phi$ within a loop of wire varies with the time, an e.m.f. is induced in the loop, the instantaneous value $e$ of the e.m.f. being proportional to the rate of change of flux;

$$e = -k\frac{\partial \Phi}{\partial t}, \tag{31}$$

where $\partial\Phi/\partial t$ is the rate of change of flux $\Phi$ with respect to the time $t$, and $k$ is a constant which depends upon the units of voltage, flux, and time. When $\Phi$ is in maxwells, $e$ in volts, and time in seconds, $k = 10^{-8}$. If the flux is expressed in webers, $k = 1$. The sign minus determines the relative directions of the flux and the e.m.f. Namely, when the circuit is closed, the induced e.m.f. tends to produce a current in the direction such as to oppose the change in flux. This latter statement follows from **Lenz's law**, which is stated by Maxwell* as follows: If a constant current flows in the primary circuit $A$, and if, by the motion of $A$, or of the secondary circuit $B$, a current is induced in $B$, the direction of this induced current will be such that, by its electromagnetic action on $A$, it tends to oppose the relative motion of the circuits. See the right-hand screw rule (Par. **56**) or Fleming's rule (Par. **57**). For practical purposes three particular cases of electromagnetic induction are considered below.

**37. Stationary conductor and variable flux.** This is the case when both the exciting m.m.f. which produces the flux, and the winding in which an e.m.f. is induced, are stationary, relatively to one another. The voltage is induced by a varying magnetic flux, the changes in the flux being produced by varying either the magnitude of the m.m.f. (stationary transformer) or

* Maxwell, J. C. "A Treatise on Electricity and Magnetism," Vol. II, Art. 542.

Digitized by Google

the reluctance of the magnetic circuit (inductor-type alternator). If the flux is linked with $N$ turns and varies harmonically with the time, at a frequency of $f$ cycles per second, the **maximum induced e.m.f.** is

$$E_{max} = 2\pi f N \Phi_{max} 10^{-8} \text{ volts}, \tag{32}$$

where $\Phi_{max}$ is the maximum instantaneous value of the flux, in maxwells. The **effective value of the induced e.m.f.** is

$$E = 4.44 f N \Phi_{max} 10^{-8} \text{ volts}. \tag{33}$$

**When the flux varies according to a law different from the sine law** the effective voltage is

$$E = 4\chi f N \Phi_{max} 10^{-8}, \tag{34}$$

where $\chi$ is the form factor (Par. **207**).

The **average e.m.f. induced in one turn**, no matter what the law of variation of the flux with the time, is

$$E_{av} = \frac{\Phi_1 - \Phi_2}{t_2 - t_1}, \tag{35}$$

where the subscripts 1 and 2 refer to the initial and the final instants respectively.

**38. Stationary flux and moving conductor.** When the exciting m.m.f. which produces the flux, and the winding in which the e.m.f. is induced, move relatively to each other, as in a generator, so that the conductors cut across the lines of flux, the instantaneous induced e.m.f. in a conductor is

$$e = k\mathfrak{B}lv, \tag{36}$$

where $\mathfrak{B}$ is the flux density, $l$ the length of the conductor, $v$ the relative velocity between the flux and the conductor, and $k$ a coefficient which depends upon the units selected. When $e$ is in volts, $\mathfrak{B}$ in maxwells per square centimeter (gausses), $l$ in centimeters and $v$ in centimeters per second, $k = 10^{-8}$.

The three directions, $\mathfrak{B}$, $l$, and $v$, are supposed to be at right angles to each other; if not, their projections at right angles to each other are to be used in the preceding formula. For practical formulas giving the e.m.f. induced in direct-current and alternating-current machinery see Sec. 7 and Sec. 8.

**39. Variable flux and moving conductor.** When coils or conductors are moving through a pulsating magnetic field, as for instance in single-phase motors, the induced e.m.f. is due to a combined transformer and generator action (Par. **37** and **38**), and is equal at any instant to the sum of the e.m.f. induced by a constant flux in a moving coil and that induced by a pulsating flux in a stationary coil. Let the frequency of the pulsating field be $f$ cycles per second; that of the rotating coil $f'$ cycles per second. A pulsating field can be resolved into two revolving fields, one rotating clockwise, the other counter-clockwise. Therefore, the induced e.m.f. is a result of the superposition of two e.m.fs., one of the frequency $f+f'$, the other $f-f'$. In the particular case of $f=f'$ the e.m.f. induced in the rotating coil is of the frequency $2f$, the frequency $f-f'$ being equal to zero.

**40. Force on a conductor carrying a current in a magnetic field.** Let a conductor carry a current of $i$ amp. and be placed in a magnetic field the density of which is $\mathfrak{B}$ maxwells per square centimeter ($\mathfrak{B}$ gausses). Then, if the length of the conductor is $l$ cm., the force tending to move the conductor across the field is

$$F = 10.2 i \mathfrak{B} l 10^{-8} \quad \text{(kg.)} \tag{37}$$

It is presupposed in this formula that the direction of the axis of the conductor is at right angles to the direction of the field. If the directions of $i$ and $B$ form an angle $\alpha$, the preceding expression must be multiplied by $\sin \alpha$.

The force $F$ is perpendicular to both $i$ and $B$, and its direction is determined by the right-hand screw rule (Par. **56**). Namely, the effect of the magnetic field produced by the conductor itself is to increase the original flux density ($\mathfrak{B}$) on one side of the conductor and to reduce it on the other side. The conductor tends to move away from the denser field.

**41. The attraction or repulsion between two parallel straight conductors,** carrying currents $i_1$ and $i_2$ (amp.) and placed in a non-magnetic medium, is calculated according to the formula

$$F = 2.04 i_1 i_2 \left(\frac{l}{b}\right) 10^{-8} \quad \text{(kg.)} \tag{38}$$

Digitized by Google

where $l/b$ is the ratio of the length of each conductor to the axial distance between the conductors. The force is an attraction or a repulsion according to whether the two currents are flowing respectively in the same or in the opposite directions.

Mechanical force exerted between magnetic flux and a current-carrying conductor is also present inside the conductor itself, and is called **pinch effect.** The force between the infinitesimal filaments of the current is an attraction, so that a current in a conductor tends to contract the conductor. This effect is of importance in some types of electric furnaces where it limits the current which can be carried by a molten conductor. The same stress also tends to elongate the conductor.

**42. Interlinkage of electric and magnetic circuits.** The most general relations between the electric and the magnetic quantities are expressed by **two laws of circuitation.*** Stripped of the vector-analysis terms in which these laws are usually expressed, they are as follows: Let $H$ be the magnetic intensity or the m.m.f. gradient at a point in a medium of constant permeability, and let $G$ be the electric intensity or the e.m.f. gradient at a point. The first law of circuitation states that the line integral of $H$ along a closed curve is proportional to the volume of the total current (conduction current and displacement current) linked with this curve. The second law of circuitation states that the line integral of the electric intensity along a closed curve is proportional to the rate of change of the total magnetic flux linked with this curve. The coefficients of proportionality depend only upon the units used. The theory of propagation of electromagnetic waves is based upon these two laws. See for instance W. S. Franklin's "Electric Waves," Art. 57.

## THE MAGNETIC CIRCUIT

**43. The simple magnetic circuit.** The simplest magnetic circuit is a uniformly wound torus ring (Fig. 5). The relation between the m.m.f. $\mathfrak{F}$ and the flux $\Phi$ is similar to Ohm's law (**19**), vis.,

$$\mathfrak{F} = \mathfrak{R}\Phi \qquad (39)$$

where $\mathfrak{R}$ is called the **reluctance** of the magnetic circuit. The same relation is sometimes written in the form

$$\Phi = \mathcal{P}\mathfrak{F} \qquad (40)$$

where $\mathcal{P} = 1/\mathfrak{R}$ is called the **permeance** of the magnetic circuit. Reluctance is analogous to resistance and permeance is analogous to conductance of an electric circuit.

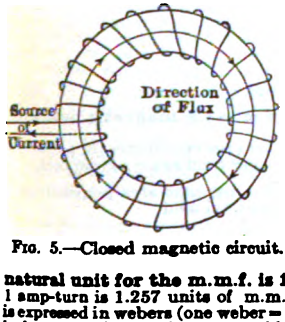

FIG. 5.—Closed magnetic circuit.

**44. The m.m.f.** does not depend alone on either the current in the winding or on the number of turns, but on the product of the two; therefore, **the natural unit for the m.m.f. is 1 amp-turn,** but in the practical system 1 amp-turn is 1.257 units of m.m.f. If the flux in the preceding equations is expressed in webers (one weber = $10^8$ maxwells) the permeance is expressed in henrys (being of the nature of inductance). It has been proposed to call the corresponding unit of reluctance the yrneh, this being the word henry spelled backward, corresponding to ohm and mho. It has also been proposed to name the unit of permeance a perm, and the unit of reluctance a rel,† when the flux is in maxwells and the m.m.f. in ampere-turns, but no names have yet been generally accepted. In the C.G.S. electromagnetic system the unit of m.m.f. is the gilbert, equal to $10/4\pi = 0.7955$ amp-turn. Therefore the m.m.f. in gilberts, expressed as a function of ampere-turns, is

$$\mathfrak{F} = \frac{4\pi}{10}nI = 1.257nI \qquad (41)$$

* Heaviside, O. "Electromagnetic Theory," Vol. I.

† Karapetoff, V. "The Magnetic Circuit;" McGraw-Hill Book Co. Inc., New York, 1912, Chap. I, and appendices.

Digitized by Google

where $nI$ is the product of the number of turns and the current in amperes. For further information about magnetic units see Sec. 1.

**45. Permeability and reluctivity.** The reluctance of a uniform magnetic path (Fig. 5) is proportional to its length $l$ and inversely proportional to its cross-section $A$, or

$$\mathcal{R} = \nu \frac{l}{A} \tag{42}$$

and

$$\mathcal{P} = \mu \frac{A}{l}. \tag{43}$$

In these expressions $\nu$ is called the reluctivity and $\mu$ the permeability of the material of the magnetic path. For air and all non-magnetic substances, $\nu$ and $\mu$ are assumed to be equal to unity per centimeter-cube, corresponding to centimeter measure for $l$ and $A$ in (42) and (43), and the gilbert as the unit of m.m.f. This is the conventional assumption in the C.G.S. electromagnetic system and is the one generally employed. See also Par. **53** and **54**.

The method preferred by the author, and expounded in his "Magnetic Circuit" (see footnote reference in Par. **44**), is to take the ampere-turn as the unit of m.m.f. In such cases, with the maxwell as the unit of flux, the permeability and the reluctivity of air, respectively, are

$$\left.\begin{aligned} \nu &= 0.7955 \text{ per cm.}^3 = 0.3132 \text{ per in.}^3 \\ \mu &= 1.257 \text{ per cm.}^3 = 3.193 \text{ per in.}^3 \end{aligned}\right\} \tag{44}$$

This method has the advantage of greater simplicity in calculations, but is not yet in general use (see Sec. 1; Giorgi system of units, Par. **3**($d_3$)).

**46. Magnetic field intensity** $\mathfrak{IC}$ is defined as the m.m.f. per unit length of path. In any uniform field

$$\mathfrak{IC} = \frac{\mathfrak{F}}{l}. \tag{45}$$

In a non-uniform magnetic circuit

$$\mathfrak{IC} = \frac{\partial \mathfrak{F}}{\partial l}. \tag{46}$$

Inversely

$$\mathfrak{F} = \mathfrak{IC} l \text{ or } \mathfrak{F} = \int \mathfrak{IC} \partial l. \tag{47}$$

$\mathfrak{IC}$ is also known as the **magnetizing force** or as the **magnetic potential gradient.**

If $\mathfrak{F}$ is in ampere-turns, $\mathfrak{IC}$ is in ampere-turns per centimeter (or per inch) of length. If $\mathfrak{F}$ is in gilberts, $\mathfrak{IC}$ is in gilberts per centimeter (or per inch).

**47. Flux density** ($\mathfrak{B}$) is defined as the flux per unit area perpendicular to the direction of the lines of force. In a uniform field

$$\mathfrak{B} = \frac{\Phi}{A}. \tag{48}$$

In a non-uniform field

$$\mathfrak{B} = \frac{\partial \Phi}{\partial A}. \tag{49}$$

Inversely

$$\Phi = \mathfrak{B} A, \text{ or } \Phi = \int \mathfrak{B} \partial A. \tag{50}$$

If the flux is measured in maxwells and areas in square centimeters, flux density is expressed in maxwells per square centimeter; one maxwell per square centimeter is sometimes called a **gauss.** In this country flux density is also expressed in maxwells, or in kilolines, per square inch.

It follows at once from (40), (43), (45) and (48) that

$$\mathfrak{B} = \mu \mathfrak{IC} \tag{51}$$

which is the familiar relationship between flux density, permeability and magnetic field intensity.

**48. Reluctances and permeances in series and in parallel.** Reluctances and permeances are added like resistances and conductances (Par. **22**

Digitized by Google

to 25), respectively. That is, *reluctances are to be added when in series, and permeances are to be added when in parallel.* If several permeances are given in connected in series they are first converted into reluctances by taking the reciprocal of each. Similarly if reluctances are given in a parallel combination, they are first converted into permeances by taking the reciprocal of each.

**49. Magnetization characteristic.** The magnetic properties of a sample of steel or iron are represented by a **saturation** or **magnetization curve** (Fig. 6). Magnetic intensities $\mathfrak{H}$ in ampere-turns per centimeter (or per inch) are plotted as abscissæ and the corresponding flux densities $\mathfrak{G}$ in kilolines per square centimeter (or per square inch) as ordinates. The curve is also known as the $\mathfrak{G}$–$\mathfrak{H}$ curve.

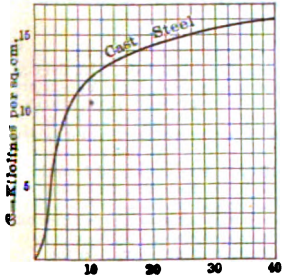

FIG. 6.—Typical $\mathfrak{G}$–$\mathfrak{H}$ curve.

The practical use of a magnetization curve may be best illustrated by an example. Let it be required to find the number of exciting ampere-turns for magnetising a steel ring so as to produce in it a flux of 168,000 maxwells. Let the cross-section of the ring be 3 cm. by 4 cm., and the mean diameter 46 cm. Let the quality of the material be represented by the curve in Fig. 6. The flux density is $168{,}000/(3\times4) = 14{,}000$ maxwells per square centimeter or 14 kilogausses. For this flux density the corresponding abscissa from the curve is about 18 amp-turns per centimeter. The total required number of ampere-turns is $18\times\pi\times46 = 2{,}600$.

It may be noted that it is much more convenient to plot curves of $\mathfrak{G}$ using as abscissæ $\mathfrak{H}$ in *ampere-turns* per unit length, rather than *gilberts* per unit length. For "$\mathfrak{G}$–$\mathfrak{H}$" curves of various grades of steel and iron see Sec. 4. The principal methods for experimentally obtaining magnetisation curves will be found in Sec. 3.

**50. In a magnetic circuit consisting partly of iron and partly of** air the ampere-turns required for establishing a certain flux are calculated by adding together the ampere-turns required for each part of the circuit. Let $\mathfrak{G}_i$ be the flux density (gausses) in the iron and $l_i$ the length (centimeters) of the path in the iron, $\mathfrak{G}_a$ the flux density in the air and $l_a$ the length of the air-gap in the direction of the lines of force. Then the total ampere-turns required for the circuit are

$$NI = \mathfrak{H}_i l_i + \mathfrak{H}_a l_a, \qquad (52)$$

where $\mathfrak{H}_i$ (ampere-turns) is found from a saturation curve for the known value of $\mathfrak{G}_i$ (**49**) and $\mathfrak{H}_a = 0.7955\mathfrak{G}_a$. If $l_a$ is in inches, and $\mathfrak{G}_a$ in maxwells per square inch, $\mathfrak{H}_a = 0.3132\mathfrak{G}_a$. The same method is applied if a magnetic circuit consists of more than two parts, as for instance the magnetic circuit of an electric generator or motor (Secs. 7 and 8). For numerous practical problems and solutions see the author's "Magnetic Circuit," pp. 27–31, and Chaps. V and VI.

**51. Analysis of magnetization curve.** Three parts are distinguished in a magnetisation curve (Fig. 6), the lower or nearly straight part, the middle part called the **knee** of the curve and the upper part which is nearly a straight line. As the magnetic intensity $\mathfrak{H}$ increases, the corresponding flux density $\mathfrak{G}$ increases more and more slowly, and the iron is said to approach **saturation.** The percentage of saturation of a machine is defined in Art. 47 of the Standardization Rules of the A. I. E. E. (Sec. 24).

**52. Susceptibility and induced magnetization.** A magnetic flux in iron or in another magnetic substance may be thought of as due to two causes: (1) the external applied m.m.f., and (2) the internal or molecular m.m.fs., induced by the applied m.m.f. Thus, we have

$$\mathfrak{H} = \kappa\mathfrak{F}, \qquad (53)$$

where $\mathfrak{H}$ is the magnetic intensity due to the external m.m.f., and $\mathfrak{F}$ is the

Digitized by Google

intensity of induced magnetization. The coefficient $\kappa$ is called the **susceptibility** of the material. The total flux density in iron also consists of two parts, viz., that due to $\mathcal{H}$ and to $\mathfrak{I}$, or, in the C.G.S. system,

$$\mathfrak{B} = \mathcal{H} + 4\pi\mathfrak{I}. \tag{54}$$

Dividing both sides of this equation by $\mathcal{H}$, gives

$$\mu = 1 + 4\pi\kappa, \tag{55}$$

where $\mu$ is the permeability of the material (Par. **52**). Susceptibility is equal to zero for non-magnetic materials, is positive for paramagnetic and negative for diamagnetic substances. It is seldom used in practice.*

**53. The permeability ($\mu$) and the reluctivity ($\nu$) of a material (Par. 45) are also defined** as the ratios

$$\mu = \frac{\mathfrak{B}}{\mathcal{H}} \text{ and } \nu = \frac{\mathcal{H}}{\mathfrak{B}}. \tag{56}$$

Their values depend upon the units selected for $\mathfrak{B}$ and $\mathcal{H}$. In the C.G.S. electromagnetic system $\mathfrak{B}$ and $\mathcal{H}$ are numerically equal for non-magnetic materials, consequently $\mu = \nu = 1$. When $\mathfrak{B}$ is expressed in maxwells per square centimeter (or per square inch) and $\mathcal{H}$ in ampere-turns per unit length, $\mu$ and $\nu$ for air and other non-magnetic materials have values given in Par. **45**, Eq. 44.

**54. Two different scales of permeability.** For steel and iron the permeability $\mu = \mathfrak{B}/\mathcal{H}$ is frequently calculated from the magnetization curve (Par. **49**), and is usually plotted against $\mathfrak{B}$ as abscissa (see curves in Sec. 4). One must be careful to distinguish between the **absolute permeability** and the **relative permeability**. The former is equal to $\mathfrak{B}/\mathcal{H}$, the latter is the ratio of the permeability of a sample to that of the air. In the C.G.S. electromagnetic system both permeabilities are numerically the same, because $\mu$ is assumed to be unity for the air; nevertheless they have different physical dimensions in any system of units.

**55. Magnetic calculations.** In practice, calculations of magnetic circuits with iron are usually arranged so as to avoid the use of permeability $\mu$ altogether, using a $\mathfrak{B}$–$\mathcal{H}$ curve directly (Par. **49** and **50**). In some special investigations it is convenient to use the values of permeability and also an empirical equation between $\mu$ and $\mathfrak{B}$. For small and medium flux densities $\mu$ may be expressed as a parabolic curve, of the form

$$\mu = a - b(\mathfrak{B}_0 - \mathfrak{B})^2 10^{-6} \tag{57}$$

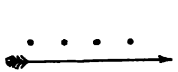

FIG. 7a.—Relation between directions of current and flux.

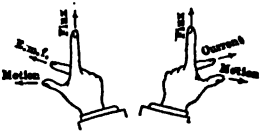

FIG. 7b.—Fleming's rules.

For numerical values of the coefficients see Sec. 4. It is also possible to represent the **relationship between $\mathfrak{B}$ and $\mathcal{H}$ for a magnetic material** empirically by a hyperbola (Fröhlich's formula)

$$\mathfrak{B} = \frac{\mathcal{H}}{\alpha + \beta\mathcal{H}}, \tag{58}$$

or also in the form

$$\text{reluctivity } \nu = \frac{\mathcal{H}}{\mathfrak{B}} = \alpha + \beta\mathcal{H} = \frac{1}{\mu}. \tag{59}$$

The coefficients $\alpha$ and $\beta$ must be so determined as to satisfy the saturation curve of the particular material used.

**56. The right-hand screw rule.** The direction of the flux produced by a given current is determined as shown in Fig. 7*a* (see also Fig. 5). If the

* Maxwell, J. C. "A Treatise on Electricity and Magnetism," Vol. II., Arts., 426 to 428.

Digitized by Google

current flows in the direction of rotation of a right-hand screw, the flux is in the direction of the progressive movement of the screw. If the current in a straight conductor is in the direction of the progressive motion of a right-hand screw, then the flux encircles this conductor in the direction in which the screw must be rotated in order to produce this motion. The dots in the figure indicate the direction of flux or current toward the reader; the crosses, that away from him.

**57. The relative direction of flux, e.m.f. and motion** in a generator may be determined with the right hand by placing the thumb, index- and middle fingers so as to form the three axes of a coordinate system and then pointing the index-finger in the direction of the flux (north to south) and the thumb in the direction of motion, the middle finger will give the direction of the generated e.m.f. (Fig. 7*b*). In the same way in a motor, using the left hand and pointing the index-finger in the direction of the flux and the middle finger in the direction of the current in the armature conductor, the thumb will indicate the direction of the force, and, therefore, the resulting motion. These two rules, indicated in Fig. 7*b*, are known as **Fleming's rules.**

**58. Laplace's law.** In a medium the permeability of which is the same at all points, the magnetic field intensity produced at a point $A$ by an element of a conductor $\partial s$ (in cm.) through which a current of $i$ amp. is flowing, is

$$\partial \mathfrak{K} = \frac{i \partial s \sin \alpha}{10 r^2} \qquad \text{(gilberts per cm.)} \qquad (60)$$

where $r$ is the distance between the element $\partial s$ and the point $A$, in centimeters and $\alpha$ is the angle between the directions of $\partial s$ and $r$. The intensity $\partial \mathfrak{K}$ is perpendicular to the plane comprising $\partial s$ and $r$, and its direction is determined by the right-hand screw rule given above. The field intensity produced at $A$ by a closed circuit is obtained by integrating the above expression for $\partial \mathfrak{K}$ over the whole circuit.

**59. The magnetic field due to an indefinite straight conductor,** carrying a current of $i$ amp., consists of concentric circles which lie in planes perpendicular to the axis of the conductor and which have their centres on this axis. The **field intensity** at a distance of $r$ cm. from the axis of the conductor is

$$\mathfrak{K} = \frac{2i}{10r} \qquad \text{(gilberts per cm.)}, \qquad (61)$$

its direction being determined by the right-hand screw rule (Par. 56).

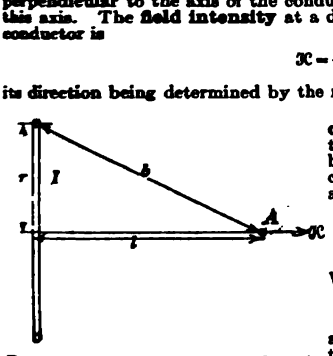

Fig. 8.—Magnetic field along the axis of a circular conductor.

**60. Magnetic field due to a closed circular conductor.** If the conductor carrying a current of $I$ amp. is bent in the form of a ring of radius $r$ cm. (Fig. 8), the magnetizing force at a point along the axis is

$$\mathfrak{K} = \frac{2\pi r^2 I}{10 b^3} = \frac{0.2\pi r^2 I}{(\sqrt{r^2+l^2})^3} \qquad \text{(gilberts per cm.)}. \qquad (62)$$

When $l = 0$

$$\mathfrak{K} = \frac{0.2\pi I}{r} \qquad (63)$$

and when $l$ is very great in comparison to $r$

$$\mathfrak{K} = \frac{0.2\pi r^2}{l^3} I. \qquad (64)$$

**61. The magnetic intensity within a solenoid** made in the form of a **torus ring,** and also in the middle part of a **long straight solenoid,** is

$$\mathfrak{K} = \frac{4\pi}{10} n_1 i \qquad \text{(gilberts per cm.)} \qquad (65)$$

where $i$ is the current in amperes, and $n_1$ is the number of turns per centimeter length.

The determination of the **field intensity produced by short coils** is

Digitized by Google

usually a complex matter, and the results are expressed by complicated formulæ. See references in Par. **74**.

**62. The stored magnetic energy** in a single loop of non-magnetic wire, when the dimensions of the wire are small compared to those of the loop (so that the flux inside the wire is negligible), is

$$W = \tfrac{1}{2} i\Phi = \tfrac{1}{2} i^2 \mathcal{P} = \frac{\Phi^2}{2\mathcal{P}} \quad \text{(joules)} \qquad (66)$$

where $i$ is the current in amperes, $\Phi$ the flux linking with the loop, in webers, and $\mathcal{P}$ the permeance of the magnetic path, in henrys.

**63. Effect of leakage.** When the flux linking with part of the turns of a coil $C$ is not negligible (see Fig. 9), the **total stored energy** may be expressed in the following forms:

$$\left.\begin{aligned} W &= \tfrac{1}{2} i[n_c \Phi_c + \Sigma n_p \Delta\Phi_p], \\ W &= \tfrac{1}{2} i^2[n^2 \mathcal{P}_c + \Sigma n_p{}^2 \Delta\mathcal{P}_p]. \end{aligned}\right\} \qquad (67)$$

The last expression is identical with

$$W = \tfrac{1}{2} L i^2 \qquad (68)$$

where $L$ is the inductance of the coil (Par. **67**). The subscripts $c$ in the foregoing expressions refer to **complete linkages**, that is those which embrace

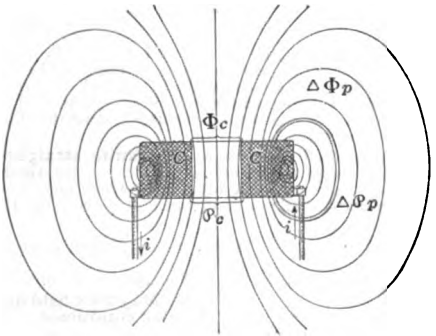

FIG. 9.—Magnetic field due to a coil.

all the turns of the coil, the subscripts $p$ **to partial linkages**. See the author's "Magnetic Circuit," Art. 57.

**64. The density of magnetic energy,** or the magnetic energy stored per cubic centimeter of a magnetic field is

$$W' = \frac{\mu \mathcal{H}^2}{8\pi} = \frac{\mathcal{B}\mathcal{H}}{8\pi} = \frac{\mathcal{B}^2}{8\pi\mu} \quad \text{(joules per cubic cm.)}. \qquad (69)$$

Here $\mathcal{H}$ is the intensity in gilberts per centimeter, $\mathcal{B}$ is the flux density in webers per square centimeter and $\mu$ is the relative permeability; or if $\mathcal{H}$ is in ampere-turns per centimeter, then

$$W' = \tfrac{1}{2}\mu\mathcal{H}^2 = \tfrac{1}{2}\mathcal{B}\mathcal{H} = \frac{\mathcal{B}^2}{2\mu} \quad \text{(joules per cubic cm.)} \qquad (70)$$

where $\mu$ is the so-called absolute permeability (see Par. **54**). To find the total energy of a field the preceding expressions are multiplied by the element of the volume $\partial v$ and integrated within the desired limits of volume. For an interesting comparison of practical possibilities as to the amount of energy stored in the magnetic form per unit volume, compared with other forms of energy, see Steinmetz, C. P., *General Electric Review*, 1913, p. 536.

Digitized by Google

**65. Magnetic tractive force.*** **The carrying weight of a lifting magnet is**

$$F = \frac{A\mathfrak{B}^2}{24.64} \qquad \text{(kg.)} \qquad (71)$$

where $\mathfrak{B}$ is the flux density in the air-gap, expressed in kilolines per square centimeter, and $A$ is the total area of the contact between the armature and the core, in square centimeters. See also Sec. 5.

**66. Magnetic force or torque.** The **mechanical force** or **the torque between two parts of a magnetic circuit** may in some cases be conveniently calculated by making use of **the principle of virtual displacements.** An infinitesimal displacement between the two parts is assumed, and the assumption is made that the work necessary for this displacement is equal to the change in the stored magnetic energy, plus the electrical energy added during the change from the source of the exciting current. For details see the author's "Magnetic Circuit," Art. 71.

## INDUCTANCE

**67. The electromagnetic inductance,** or **the coefficient of self-induction** $L$, **is defined from any of the following three fundamental equations:**

$$e = -L\frac{di}{dt}; \qquad (72)$$

$$W = \tfrac{1}{2}i^2L; \qquad (73)$$

$$L = n_c{}^2\mathcal{P}_c + \int_0^n n_p{}^2 d\mathcal{P}_p. \qquad (74)$$

**These expressions are true only when the permeability of the medium is constant. The first equation expresses the fact that the self-induced voltage is proportional to the rate of change of the current in the circuit, and $L$ is the coefficient of proportionality. According to the second equation, the magnetic energy stored in a circuit is proportional to the square of the current (Par. 63), and $L$ is the coefficient of proportionality. In the third formula $L$ is expressed through the permeances $\mathcal{P}$ of the magnetic paths linking with the circuit (Fig. 9), and the number of turns with which these paths are linked. The subscripts $c$ and $p$ refer to complete and partial linkages respectively (Par. 62). For practical purposes both inductance and permeance are expressed in henrys (Par. 44). The first expression is convenient for measurements of inductance, the third one for calculations in those cases where the shape of the magnetic paths is known or can be estimated.**

**68. Closed magnetic circuit.** For a **torus ring** (Fig. 5) **uniformly wound with one layer of thin wire** the partial linkages may be neglected, so that $n_p = 0$, and $\mathcal{P}_c = \mu A/l$, where for non-magnetic materials $\mu = 1.000$; $A$ is the cross-section of the flux within the ring, and $l$ is the average length of the flux. Consequently

$$L = \frac{1.257 n_c{}^2 A}{l}\mu_r 10^{-8} = 1.257 n_1{}^2 l A 10^{-8} \qquad \text{(henrys)} \qquad (75)$$

In this expression $n_c$ is the total number of turns, and $n_1 = n_c/l$ is the number of turns per centimeter length of the magnetic path; $l$ and $A$ are in square centimeters; $\mu_r$ is the relative permeability of the core with respect to the air (Par. 54).

**69. For a torus ring of rectangular cross-section wound with several layers of wire the inductance is**

$$L = 0.4\frac{n^2}{D}[bh + \frac{2}{3}t(b + h + t)]10^{-8} \qquad \text{(henrys)} \qquad (76)$$

In this expression $b$ and $h$ are the dimensions of the non-magnetic core on which the wire is wound, $D$ is the mean diameter of the ring, $n$ is the total number of turns, and $t$ the thickness of the winding (all in centimeters). If the core is magnetic, the product $bh$ must be multiplied by the relative

* Maxwell, J. C. "Treatise on Electricity and Magnetism;" Cambridge University Press; Vol. II, Art. 643.

Digitized by Google

permeability of the steel. If the magnetic core occupies only a part $\alpha$ of the cross-section $bh$, use the expression $bh[\alpha\mu_r+(1-\alpha)]$, in place of $bh$.

**70. For other calculations of inductance** using formula (68) see the author's "Magnetic Circuit," Chaps. X to XII.

**71. Thin solenoids.** For a straight coil uniformly wound with $n_1$ turns per centimeter length, provided that the length of the coil is large compared to its transverse dimensions, and that the winding consists of one layer of comparatively thin wire, **the inductance is**

$$L = 1.257 n_1^2 A 10^{-8} \quad \text{(henrys)} \qquad (77)$$

the notation being the same as in Par. 68.

**72. The inductance of a long straight coil** wound with several layers of wire, and with an iron core of radius $a$ inside,

$$L = 4n_1^2 l d^2 r^2 \left[1 + (\mu_r - 1)\frac{a^2}{r^2} + \frac{d}{r} + \frac{d^2}{3r^2}\right] 10^{-9} \quad \text{(henrys)} \qquad (78)$$

where $r$ is the inside radius of the winding, and $d$ its radial thickness; $n_1$ is the number of turns per centimeter length, and all the dimensions are in centimeters. If there is no iron core, put $a = 0$.

**73. Prof. Morgan Brooks** has derived a universal semi-empirical formula for the **inductance of short and long coils without iron cores.** His formula is given below in two forms, one (79) for dimensions in centimeters, the other (80) for dimensions in English units. Both give results in henrys. The notation is explained in Fig. 10.

$$L = \frac{Cm^2}{b+c+R} \times \frac{F'F''}{10^9} \quad \text{(henrys)} \qquad (79)$$

$$L = \frac{0.366\left(\frac{Ft}{1000}\right)^2}{b+c+R} \times F'F'' \quad \text{(henrys)} \qquad (80)$$

In Eq. (80) the conductor length is in thousands of feet, and the coil dimensions in inches; 0.366 is the conversion factor. $F'$ and $F''$ are empirical coil-shape factors dependent upon the relative, and independent of the absolute dimensions of the winding. Values of $F'$ and $F''$ are as follows:

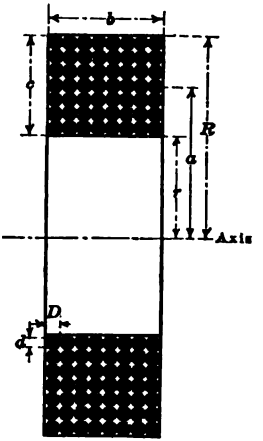

FIG. 10.—See Par. 73.

$$F' = \frac{10b+12c+2R}{10b+10c+1.4R}; \quad F'' = 0.5 \log_{10}\left(100 + \frac{14R}{2b+3c}\right). \qquad (81)$$

$Cm$ indicates the length of the conductor in centimeters;
$Ft$ indicates the length of the conductor in feet, and $Ft/1000$ = thousands of feet;
$N$ is the total number of turns in the winding, whence

$$Cm = 2\pi aN, \text{ when } a \text{ is in centimeters, and} \qquad (82)$$

$$\frac{Ft}{1000} = \frac{2\pi aN}{12000} \text{ when } a \text{ is in inches.} \qquad (83)$$

Numerous tables, curves, and charts which simplify the use of this formula for practical design will be found in the Bulletin No. 53 of the University of Illinois, by Morgan Brooks and H. M. Turner, entitled "Inductance of Coils." For another empirical formula see Doggett, L. A., "The Inductance of Air-cored Solenoids," *Elec. World*, Vol. LXIII (1914), p. 259.

**74. Bureau of Standards, formulas for inductance.** For a thorough analysis and comparison of various formulas for the inductance of coils the reader is referred to the following excellent series of articles published in the Bulletin of the Bureau of Standards:

"Formulæ and Tables for the Calculation of Mutual and Self-inductance" (Revised), E. B. Rosa and L. Cohen, Vol. VIII, p. 1; 1912; "Calculation of

Digitized by Google

the Self-inductance of Single-layer Coils," Edward B. Rosa. Vol. II, p. 161; 1906; "The Self-inductance of a Coil of any Length Wound with any Number of Layers of Wire," Edward B. Rosa. Vol. IV, p. 369; 1907; "Self-Inductance of a Solenoid of any Number of Layers," Louis Cohen. Vol. IV, p. 383; 1907; "Construction and Calculation of Absolute Standards of Inductance," J. G. Coffin. Vol. II, p. 37; 1906.

"Revision of the Formulas of Weinstein and Stefan for Mutual Inductance of Coaxial Coils," Edward B. Rosa. Vol. II, p. 331; 1906; "The Mutual Inductance of Two Circular Coaxial Coils of Rectangular Section," Edward B. Rosa and Louis Cohen. Vol. II, p. 359; 1906. See also E. Orlich, "Kapazität und Induktivität" (Vieweg), p. 74. and Louis Cohen, "Formuls and Tables for the Calculation of Alternating-current Problems," Chap. 2.

**76. The inductance of a concentric cable** is (Fig. 11)

$$L = 0.4605 \log_{10}\left(\frac{b}{a}\right) + 0.05 + L' \quad \text{(millihenrys per km.)} \quad (84)$$

where

$$L' = \frac{t}{15b}\left[1 - \frac{1}{10}\left(\frac{t}{b}\right)^2 + \frac{3}{40}\left(\frac{t}{b}\right)^6 + \ldots\right] \quad (85)$$

The foregoing expression for $L$ is true at **low frequencies** only. At high frequencies an unequal distribution of currents reduces the partial linkages so that in general

$$L = 0.4605 \log_{10}\left(\frac{b}{a}\right) + k(0.05 + L'). \quad (86)$$

Here $k = 1$ at usual industrial frequencies, and gradually approaches zero as the frequency increases to infinity.

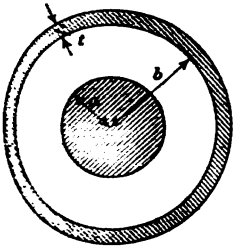

FIG. 11.—Cross-section of concentric cable.

**76. N-conductor cables.** For the **field distribution** in and the **inductance of non-concentric cables** see Alex. Russell, "Alternating currents," Vol. I; for the **inductance of armored cables** see J. B. Whitehead, "The Resistance and Reactance of Armored Cables," Trans. A. I. E. E., Vol. XXVIII (1909), p. 737.

**77. The inductance of a single-phase transmission line** is given by

$$L = 0.4605 \log_{10}\frac{b}{a} + 0.05, \text{ in millihenrys per kilometer of one conductor,} \quad (87)$$

where $a$ is the radius of the conductors, and $b$ is the distance between their centres. To find the inductance per mile multiply by 1.609. To find the inductance per thousand feet divide by 3.281. For tables of reactance (Par. **154**) at usual frequencies and spacings see Sec. 11.

**78. For iron conductors** use $0.05\mu_r$ instead of 0.05 in the above formula, where $\mu_r$ is the relative permeability of the iron with respect to the air. The value of $\mu_r$ varies with the current, and also depends upon the quality of the iron. For good telegraph wire $\mu_r$ is equal approximately to 150.

**79. For stranded conductors** the actual radius is too large to be used in the formula for inductance. For all practical purposes, the equivalent radius of a stranded conductor may be assumed the same as that of a solid round conductor of the same sectional area. For an accurate calculation of the inductance of stranded conductors see Dwight, H. B., *Electrical World*, 1913, Vol. LXI, p. 828.

**80. The inductance of a three-phase line with symmetrical spacing, per wire,** is the same as the inductance of a single-phase line per wire, with the same size of wire and the same spacing. It is expressed by the formula (87) in Par. **77**. This formula holds true for balanced as well as unbalanced loads, for balanced and unbalanced line voltages, for a three-wire two-phase system, three-wire single-phase system, monocyclic system, etc.

**81. For a semi-symmetrical spacing of a three-phase line,** that is when two spacings are equal, and the third is different, formula (87) in

Digitized by Google

Par. 77 holds true only for the conductor situated symmetrically with respect to the other two. The inductance of the other two wires cannot be calculated in a simple manner. For practical purposes it is sufficient to take the inductance of all three wires as equal to that of a line symmetrically spaced, the equivalent spacing being equal to the geometric mean of the three actual spacings, or

$$b_{eq} = \sqrt[3]{b_1 b_2 b_3}. \qquad (88)$$

**82. For the equivalent resistance and reactance of a three-phase line with unequal spacings of wires** see the writer's "Magnetic Circuit", Art. 63. In this case the e.m.f. induced in a conductor by the varying magnetic fluxes consists of two components, one being in quadrature, the other in phase with the current in the conductor. The first component corresponds to the inductance of the conductor, the other represents transfer of power from one phase to the others. In general, these components are different for the three conductors, and in order to equalize them for the whole line conductors are transposed after a certain number of spans. This **transposition of conductors** is used on power lines (Sec. 11) as well as on telegraph and telephone lines (Sec. 21) to reduce the unbalancing effect of mutual induction. See also Par. 87 below. The inductance of two or more parallel cylinders of any cross-section can be expressed through the so-called geometric mean distance introduced by Maxwell.* For details also see Orlich, "Kapazätit und Inductivität," pp. 63–74.

**83. Mutual inductance.** When two independent electric circuits, (1) and (2), are in proximity to each other, their electromagnetic energy may be said to consist of three parts: the part due to the linkages of the flux produced by the circuit (1) with the current in (1); that due to the flux produced by the circuit (2) with the current in (2); and that due to the current in each circuit linking with the flux produced by the other circuit. Employing the notation in Par. 67, the total energy of the system is expressed by

$$W = \tfrac{1}{2} i_1^2 L_1 + \tfrac{1}{2} i_2^2 L_2 + i_1 i_2 L_m \quad \text{(joules)} \qquad (89)$$

where $L_1$ and $L_2$ are the coefficients of self-induction of the two circuits, and $L_m$ is called the **coefficient of mutual inductance** of the two circuits. All three coefficients are measured in henrys.

**84. The coefficient of mutual inductance** is also defined from the relations:

$$e_1 = -L_m \frac{di_2}{dt}, \text{ or } e_2 = -L_m \frac{di_1}{dt}, \qquad (90)$$

that is, $L_m$ determines the voltage $e_1$ induced in the circuit (1) when the current $i_2$ in circuit (2) varies with the time, and *vice versa*.

**85. The coefficient of mutual inductance of two long coaxial single-layer coils** of the same length $l$ and cross-section $A$, is

$$L_m = 1.257 n_1 n_2 l A 10^{-8}, \text{ (henrys)}, \qquad (91)$$

where $n_1$ and $n_2$ are the numbers of turns per centimeter length of the two coils respectively; $l$ and $A$ are measured in centimeters.

**86. For two long coaxial coils wound in several layers the coefficient of mutual inductance** is

$$L_m = 4\pi n_1^2 n_2^2 l d_1 d_2 r_1^2 \left(1 + \frac{d_1}{r_1} + \frac{d_1^2}{3 r_1^2}\right) \quad \text{(henrys)} \qquad (92)$$

and if an iron core is present

$$L_m = 4\pi n_1^2 n_2^2 l d_1 d_2 r_1^2 \left[1 + (\mu_r - 1)a^2 + \frac{d_1}{r_1} + \frac{d_1^2}{3 r_1^2}\right] \quad \text{(henrys)} \qquad (93)$$

For explanation of notation see Par. 72 above. See also the references in Par. 74.

**87. The coefficient of mutual inductance of two parallel line circuits** (Fig. 11*a*) is given by

$$L_m = 0.4605 \log_{10}\left(\frac{a_1 b_2}{b_1 a_2}\right) \quad \text{(millihenrys per km.)} \qquad (94)$$

where $a_1$ and $b_1$ are the distances from one of the wires of circuit 1 to the

* Maxwell, J. C. "Treatise on Electricity and Magnetism," Vol. II, p. 324.

Digitized by Google

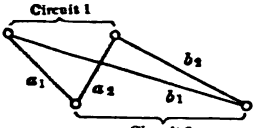

FIG. 11a.

conductors of the other circuit, and $a_2$ and $b_2$ are the corresponding distances of the other wire of circuit 1 from the conductors of the other circuit. For **interference between transmission and telephone lines** due to mutual inductance see Sec. 21. Transposition of telephone lines is also explained in Sec. 21.

**88. Actual measurement** must be employed in most cases to determine the coefficient of **mutual inductance.** See Sec. 3.

## HYSTERESIS AND EDDY CURRENTS

**89. The hysteresis loop.** When a sample of iron or steel is subjected to an alternating magnetisation, the relation between $\mathfrak{G}$ and $\mathfrak{K}$ (Par. 49) is different for increasing and decreasing values of the magnetic intensity (Fig. 12). This phenomenon may be thought of as due to some kind of friction between the molecules of the magnetic material. Each time the current wave completes a cycle, the magnetic flux wave must also complete a cycle and each molecular magnet be turned through one revolution. This loss appears as heat. The figure *AefBcdA* in Fig. 12 is called the hysteresis loops.

**90. Retentivity.** If the coil shown in Fig. 5 be excited with alternating current, the ampere-turns and consequently the m.m.f. will, at any instant, be proportional to the instantaneous value of the exciting current. Plotting a $\mathfrak{G}$–$\mathfrak{K}$ or a $\Phi$–$\mathfrak{F}$ curve (Fig. 12) for one cycle, the closed loop, *cdAefB*, is obtained. The first time the iron is magnetized the **virgin** or **neutral curve**, *OA*, will be produced; but it cannot be produced in the reverse direction, *AO*, because when the m.m.f. drops to zero there will always be some magnetism (+*Oe* or −*Oc*) left. This is called **residual magnetism** and in order to reduce this to zero, an m.m.f. (−*Of* or +*Od*) of opposite polarity must be applied. This m.m.f. is called the **coercive force.**

**91. Wave distortion.** If the instantaneous values of the exciting current *I* (which are directly proportional to the m.m.f.) and $\Phi$ are plotted with time (Fig. 12) it is seen that if the coil is connected across a sine-wave e.m.f., the current wave will be badly distorted and displaced from the e.m.f. wave, which is in time quadrature with the flux wave, as shown at the left in Fig. 12. On the other hand, if the coil is connected in series and the current forced to follow the sine curve, the flux wave is distorted and displaced from the current wave, as shown at the right in Fig. 12.

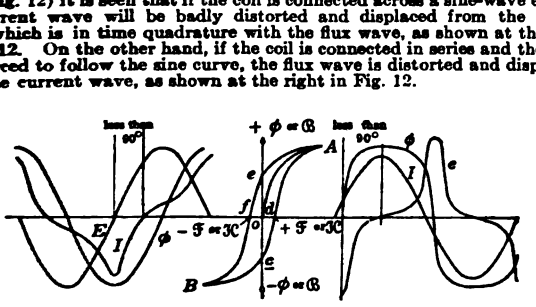

FIG. 12.—Periodic waves of current, flux and e.m.f.; hysteresis loop.

**92. Components of exciting current.** The alternating current which flows in the exciting coil (Fig. 12) may be considered to consist of two components, one exciting magnetism in the iron, and the other supplying the hysteresis loss. For practical purposes both components may be replaced by equivalent sine-waves, and finally by vectors (Fig. 13). We have

$I_r = I \cos \theta$ = power component of the current;
$P_h = IE \cos \theta = I_r E$ = hysteresis loss in watts,
$I_m = I \sin \theta$ = magnetising current,

Digitized by Google

wherein $I$ is the total exciting current and $\theta$ the angle of time-phase displacement.

The **energy lost per cycle** can be represented by the area, $AfBd$, of the loop; see Par. 94 below.

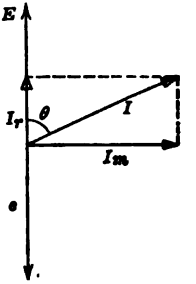

FIG. 13.—Components of exciting current; hysteretic angle.

**93. Hysteretic angle.** Without hysteresis, the current $I$ would be in phase quadrature with $E$. For this reason the angle $\alpha = 90 - \theta$ is called **the angle of hysteretic advance of phase.**

$$\text{Sin } \alpha = \frac{I_r}{I} = \frac{I_r E}{IE} = \frac{\text{watts loss}}{\text{apparent watts}}. \qquad (95)$$

In practice, the measured loss usually includes eddy currents (Par. 98) so that the name "hysteretic" is somewhat of a misnomer.

**94. The energy lost per hysteresis cycle** (Fig. 12) is proportional to the area of the loop, or

$$\text{Energy} = cV \sum_{-\mathfrak{B}}^{+\mathfrak{B}} \mathfrak{H}\Delta\mathfrak{B} \qquad \text{(joules)} \qquad (96)$$

wherein $V$ is the volume of the iron, $\mathfrak{B}$ and $\mathfrak{H}$ being the coordinates of the loop instead of $\Phi$ and $\mathfrak{F}$ as shown in Fig. 12; and $c$ a constant depending upon the scale used. For details see the author's "Magnetic Circuit," Art. 16.

**95. Steinmetz's formula.** According to exhaustive experiments by Dr. C. P. Steinmetz, the heat energy released per cycle per cubic centimeter of iron is approximately

$$W = \eta B^{1.6}_{max} \qquad \text{(ergs)} \qquad (97)$$

The exponent of $\mathfrak{B}$ varies between 1.4 and 1.8 but is generally taken as 1.6. Values of $\eta$ are given in Sec. 4 (see index).

**96. Power loss per unit weight.** The most convenient way to express the **hysteresis loss** is

$$P_h = k_h \frac{f}{100}\left(\frac{\mathfrak{B}_{max}}{1000}\right)^{1.6} \qquad \text{(watts per unit weight)} \qquad (98)$$

wherein $f$ is the frequency in cycles per second; $\mathfrak{B}$ the maximum flux density in lines or maxwells per square centimeter, and $k_h$ a constant; see Sec. 4.

**97. Two-term formula.** Another empirical formula for the **hysteresis loss** is

$$P_h = f(\eta' B + \eta'' B^2) \qquad \text{(watts per unit weight)} \qquad (99)$$

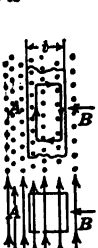

FIG. 14. Eddy currents.

where $\eta'$ and $\eta''$ are empirical coefficients. This formula is more accurate at medium and high flux densities than the preceding one.

**98. Eddy-current losses** are $I^2R$ losses (Par. 27) due to secondary currents (Foucault currents) established in those parts of the circuit which are interlinked with alternating or pulsating flux. Referring to Fig. 14, a bar-shaped conductor is just entering a non-uniform field. The advancing side, $A$, is cutting more lines than the trailing side, $B$, so that there is a difference in potential between these two sides and electricity will flow as shown by the arrows. The value of the currents, according to Ohm's law, is directly proportional to the e.m.f. and inversely proportional to the resistance of the path. The e.m.f. is directly proportional to the thickness, $t$, of the bar, but the length of the path, and therefore its resistance, is but slightly altered by varying the thickness, $t$.

Referring to Fig. 15, which shows a cross-section of a transformer core, the primary current, $I$, produces the alternating flux, $\Phi$, which by its change generates an e.m.f., $e$, in the core; this e.m.f. then sets up the secondary

Digitized by Google

current, $i$. Now, if the core be divided into two (*b*), four (*c*), or $n$ parts, the same total e.m.f. will be generated but the e.m.f. in each circuit will be $e/2$, $e/4$, $e/n$ respectively, whatever the length of the circuit, and therefore the resistance will not be materially altered.

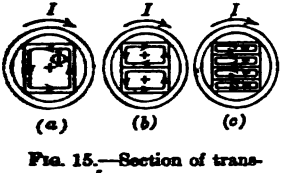

FIG. 15.—Section of transformer core.

**99. Effect of lamination.** From the two examples given above it is seen that the eddy currents can be greatly reduced by laminating the circuit, *i.e.*, by making it up of thin sheets each insulated from the others. The same purpose is accomplished by using stranded conductors or bundles of wires. **The eddy-current loss in a laminated iron core is**

$$P_e = k_e \left(\frac{t f \mathfrak{B}_{max}}{1000}\right)^2, \quad \text{(watts per unit weight)} \quad (100)$$

**wherein** $t$ **is the thickness of the laminations in mils;** $f$ **the frequency in cycles per second, and** $k_e$ **a factor including the specific weight and resistivity of the material.**

**The determination of values of the constant,** $k_e$**, for different materials is treated in Sec. 4 (see index).**

**A formula for the loss in conductors of circular section, such as wire, is**

$$P_e = \frac{(\pi r f \mathfrak{B}_{max})^2}{4\rho\ 10^{16}} \quad \text{(watts per cu. cm.)} \quad (101)$$

**wherein** $r$ **is the radius of the wire in centimeters;** $f$ **the frequency in cycles per second;** $\mathfrak{B}_{max}$ **is the maximum flux density in lines per square centimeter and** $\rho$ **the specific resistance of the wire, *i.e.*, the resistance in ohms per centimeter cube.**

**A formula for the loss in sheets is**

$$P_e = \frac{(\pi t f \mathfrak{B}_{max})^2}{6\rho\ 10^{16}} \quad \text{(watts per cu. cm.)} \quad (102)$$

**wherein** $t$ **is the thickness in centimeters;** $f$ **the frequency in cycles per second;** $\mathfrak{B}_{max}$ **is the maximum flux density in lines per square centimeter, and** $\rho$ **the specific resistance.**

**The specific resistance of various materials is given in Sec. 4 (see index).**

**100. Real or ohmic resistance** is the resistance offered by the conductor to the passage of electricity. Although the specific resistance is the same for either alternating or continuous current, the total resistance of a wire is greater for alternating than for continuous current. This is due to the fact that in a conductor which is continuously cut by flux, there are generated e.m.fs.; these e.m.fs. are greater at the centre than at the circumference so that the potential difference tends to establish currents which oppose the main current at the centre and assist it at the circumference. The result is, that the main current is forced to the outside thus reducing the effective area of the conductor. This phenomenon is called skin effect (Par. 101).

**101. A theoretical formula for the calculation of skin effect is***

$$r = R\left[1 + \frac{1}{12}\left(\frac{2\pi f l \mu}{R 10^9}\right)^2 - \frac{1}{180}\left(\frac{2\pi f l \mu}{R 10^9}\right)^4 + \text{etc.}\right] \quad \text{(ohms)}, \quad (103)$$

**wherein** $r$ **is the resistance offered to an alternating current;** $R$ **that offered to a continuous current;** $f$ **the frequency in cycles per second,** $\mu$ **the relative permeability of the conductor and** $l$ **the length of the conductor in centimeters.**

It will be noted that $1/R$ is proportional to the area of cross-section of the conductor; therefore, the skin effect depends upon the area of cross-section of the conductor and the frequency of the current. These should be kept as small as possible, although skin effect seldom cuts any great figure where moderate sized conductors are used to carry current at ordinary frequencies. It is in iron or other magnetic materials, where skin effect becomes really important. It must be considered in rail returns for alternating-current systems. Skin effect tables are given in Sec. 4 (see index). For a detailed

* Maxwell, J. C. "A Treatise on Electricity and Magnetism," Vol. II, Art. 690.

Digitized by Google

treatment of resistance to alternating currents and eddy current losses in metallic conductors see Louis Cohen, "Formulæ and Tables for the Calculation of Alternating-current Problems," Chap. I. Numerous tables and formulæ will be found there, relating to the resistance to alternating currents and eddy current losses in solid, hollow and concentric cylindrical conductors, flat conductors, coils and conductors in slots of laminated iron armatures.

**102. Effective resistance and reactance.** When an alternating-current circuit has appreciable hysteresis, eddy currents and skin effect, it can be replaced by an equivalent circuit, without these losses, by using **equivalent resistances** and **equivalent reactances** (Par. **154**) in place of the real ones. These equivalent or effective quantities are so chosen that the energy relations are the same in the equivalent circuit as in the actual one. In a series circuit let the true power lost in ohmic resistance, hysteresis, and eddy currents be $P$, and the reactive (wattless) volt-amperes $P'$. Then the effective resistance and reactance are determined from the relations

$$i^2 r_{eff} = P; \quad i^2 x_{eff} = P'. \tag{104}$$

In a parallel circuit, with a given voltage, the equivalent conductance and susceptance (Par. **162**) are calculated from the relations

$$e^2 g_{eff} = P; \quad e^2 b_{eff} = P'. \tag{105}$$

Such equivalent electric quantities which replace the core loss are used in the analytical theory of transformers and induction motors.

**103. Core loss.** In practical calculations of electrical machinery the total core loss is of interest rather than the hyteresis and the eddy currents separately. For such computations empirical curves are used, obtained from tests on various grades of steel and iron (see Sec. 4).

**104. The separation of hysteresis from eddy currents.** For a given sample of laminations, the total core loss $P$, at a constant flux density and at variable frequency $f$, can be represented in the form

$$P = af + bf^2 \tag{106}$$

where $af$ represents the hysteresis loss and $bf^2$ the eddy or Foucault-current loss, $a$ and $b$ being two constants. If we write this equation for two known frequencies, two simultaneous equations are obtained from which $a$ and $b$ are determined.

**105. Determination of constants.** It is convenient to divide the foregoing equation by $f$, because in the form

$$\frac{P}{f} = a + bf \tag{107}$$

it represents the equation of a straight line between $(P/f)$ and $f$. Having plotted the known values of $(P/f)$ against $f$ as abscissæ, the most probable straight line is drawn through the points thus obtained. The intersection of this line with the axis of ordinates gives $a$; $b$ is calculated from the preceding equation. Knowing $a$ and $b$, the separate losses are calculated at any desired frequency from the expressions $af$ and $bf^2$ respectively.

## THE DIELECTRIC CIRCUIT

**106. Dielectric flux.** When a source of continuous voltage $E$ (Fig. 16) is applied at the terminals of a **condenser** $AB$, a quantity of electricity $Q$ flows through the connecting wires and the same quantity of electricity may be said to be displaced through the dielectric between the condenser terminals, because electricity behaves like an incompressible fluid. This displaced electricity in a dielectric is called the dielectric flux and is measured in the same units as a quantity of electricity in a conducting circuit; that is, in coulombs or in microcoulombs.

**107. The dielectric flux density and the potential gradient.** The flux density $D$ or the dielectric flux per unit area is $D = Q/A$ when the flux distribution is uniform, or $D = \partial Q/\partial A$ when the flux distribution is non-uniform. In these expressions $Q$ is the dielectric flux and $A$ is the area perpendicular to the electrostatic lines of force. Flux density is measured in microcoulombs per square centimeter or per square inch.

The voltage $E$ applied at the terminals of the condenser acts upon the whole thickness $l$ of the dielectric, and the **dielectric stress** $G$ is characterized as the voltage per unit thickness (unit length) of the dielectric in the direction

Digitized by Google

of the lines of force. Thus, in a uniform field, $G = E/l$, and in a non-uniform field, $G = \partial E/\partial l$. The dielectric stress $G$ is also called the **voltage gradient** or the **electric force.** It is measured in volts per inch, kilovolts per mm., or in other such convenient units. In a homogeneous dielectric, the flux density $D$ at any point is proportional to the voltage gradient at that point, and the ratio of the two characterises the material; or, $D = \kappa G$, where $\kappa$ is called the **absolute permittivity** of the dielectric. See Par. **113** and **134.**

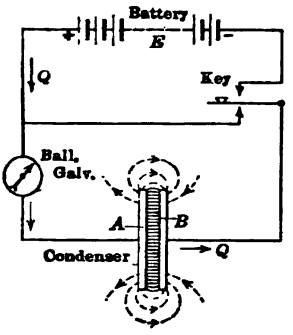

FIG. 16.—Circuit containing a condenser.

**108. Electrostatic capacity (or permittance).** The displacement $Q$ of electricity through a dielectric is proportional to the voltage $E$ applied between the terminals (Fig. 16) as long as the safe limit of insulation is not exceeded; or

$$Q = CE \tag{108}$$

where the coefficient of proportionality $C$ is called the electrostatic capacity or permittance of the condenser. When $E$ is in volts and $Q$ in coulombs, $C$ is in farads. If $Q$ is in microcoulombs, $C$ is in microfarads.

When the applied voltage is variable, the preceding equation is written in the form

$$i_c = \frac{\partial Q}{\partial t} = C\,\frac{\partial E}{\partial t}, \tag{109}$$

where $Q$ and $E$ are differentiated with respect to time $t$, and $i_c$ is called the **charging** or **displacement current.** Either this equation or the relation $Q = CE$ may be considered as the fundamental one defining capacity $C$.

**109. Elastance.** The same proportionality between the applied voltage and the displacement of electricity is sometimes written in the form

$$E = SQ, \tag{110}$$

where $S = 1/C$ is called the **elastance** of the condenser. When $E$ is in volts and $Q$ in coulombs, $S$ is measured in units which the author has termed "darafs" (farad spelled backward). When $Q$ is in microcoulombs, $S$ is in "megadarafs."

**110. Condensers in series and in parallel.** When condensers are connected in parallel, the equivalent capacity is equal to the sum of all the capacities of the component condensers, or

$$C_{eq} = \Sigma C. \tag{111}$$

When two or more condensers are connected in series, the equivalent capacity is determined from the relation

$$\frac{1}{C_{eq}} = \Sigma \frac{1}{C}. \tag{112}$$

Analogously, for a **series connection of elastances** (Par. **109**)

$$S_{eq} = \Sigma S; \tag{113}$$

and for **parallel connection of elastances**

$$\frac{1}{S_{eq}} = \Sigma \frac{1}{S}. \tag{114}$$

**111. For example,** let two permittances $C_1 = 0.2$ mf. and $C_2 = 0.3$ mf. be connected in parallel with each other, and in series with a third condenser for which $C_3 = 0.4$ mf. To find the total capacity of the combination we note that the combined capacity of the two condensers in parallel is $C_1 + C_2 = 0.5$ mf., or the elastance of the combination is two megadarafs. The elastance of the third condenser is $1/C_3 = 2.5$ megadarafs, so that the total elastance of the combination is $2 + 2.5 = 4.5$ megadarafs. Consequently the equivalent capacity is $1/4.5 = 0.222$ mf. This example shows the convenience of using elastances when condensers are connected in series.

**112. The specific inductive capacity of a dielectric** ($k$) is the ratio between the capacity of a condenser made entirely of this dielectric and of an identical condenser using air for dielectric. It is also termed the **dielectric constant.** Another name for specific inductive capacity is **relative permittivity.** For numerical values for various dielectrics see Sec. 4.

**113. Capacity (permittance) between parallel plates.** When a condenser consists of two parallel plates the distance between which is small compared to the dimensions of the plates, the lines of electrostatic displacement are nearly straight lines normal to the adjacent surfaces of the plates. The capacity of such a condenser is

$$C = \left(\frac{k}{4\pi}\right)\frac{A}{l} \qquad \text{(abstatfarads)} \qquad (115)$$

where $A$ is the area of one of the plates in sq. cm., $l$ the normal distance between them, in cm. and $k/4\pi$ the **permittivity** of the dielectric; $k$ is the dielectric constant, which for air is unity. If $C$ is to be in microfarads, then in the preceding formula in place of $k/4\pi$ use

$$\frac{k}{4\pi}\left(\frac{1}{v^2}\right) = 0.08842 \times k \times 10^{-6} \quad \text{(mf. per centimeter-cube)} \qquad (116)$$

where $v$ is the velocity of light, or the factor required to change from electrostatic to electromagnetic units.

If instead of taking $k/4\pi$ as the permittivity, a term $k_a$ called the absolute permittivity is introduced, then

$$C = k_a\frac{A}{l} \qquad \text{(microfarads)} \qquad (117)$$

And for air, instead of unity (the relative permittivity), the absolute permittivity is

$$\kappa_a = 0.08842 \times 10^{-6} \qquad \text{(mf. per centimeter-cube)} \qquad (118)$$

and for any other substance the absolute permittivity would be $0.08842 \times 10^{-6}k$, where $k$ is the specific inductive capacity or the relative permittivity of the dielectric; see Par. 112. See also the author's "Electric Circuit," Article 51, for further elaboration of this theory of absolute versus relative permittivities. At present the accepted method of calculation is based on the use of formulæ (115) and (116).

**114. The elastance of a dielectric between two parallel plates** a short distance apart is $S = \sigma\,(l/A)$ where the coefficient $\sigma$ (sigma) is called the **elastivity of the dielectric.** If $S$ is in megadarafs (1 daraf is the reciprocal of 1 farad) and the dimensions in centimeters, $\sigma$ is in megadarafs per centimeter cube. Elastance is the reciprocal of permittance, or $S = 1/C$, and, likewise, elastivity is the reciprocal of permittivity, or $\sigma = 4\pi/k$ Therefore

$$S = \left(\frac{4\pi}{k}\right)\frac{l}{A} = \sigma\,\frac{l}{A} \qquad (119)$$

For air, in practical units,

$$\sigma = 11.31 \times 10^6 \text{ mgd. per centimeter cube.} \qquad (120)$$

Example; to calculate the capacity of a plate condenser (Fig. 16) built according to the following specifications: The metal plates are 50 cm. by 70 cm. each, placed at a normal distance of 0.3 cm. The dielectric consists of three consecutive layers of insulation, which are 0.12 cm., 0.07 cm. and 0.11 cm. thick. The relative permittivities of the materials are 2, 3 and 5 respectively. Since elastances are added in series (Par. 110), the total elastance of the condenser is

$$S = [11.3 \times 10^6/(50 \times 70)][0.12/2 + 0.07/3 + 0.11/5]$$
$$= 0.34 \times 10^3 \text{ mgd.}$$

Hence the capacity $C = S^{-1} = 2.94 \times 10^{-3}$ mf.

**115. Capacity of concentric cables.** For a single-conductor cable with a grounded metal sheath (Fig. 17) the capacity

$$C = \frac{0.03882k}{\log_{10}(b/a)} \quad \text{(mf. per mile) or}$$
$$C = \frac{0.02413k}{\log_{10}(b/a)} \quad \text{(mf. per km.)} \qquad (121)$$

Digitized by Google

where $k$ is the relative permittivity of the dielectric (Par. 112). The same formula applies for the capacity or permittance between any two concentric cylinders, provided that their axial length is considerable as compared to their radii so that the effect of the ends may be neglected.

**116. Graded insulation.** When the insulation between two concentric cylinders consists of several concentric layers (Fig. 17), the elastance of the cable is:

$$S = C^{-1} = 25.75[k_1^{-1} \log_{10}(b_1/a) + k_2^{-1} \log_{10}(b_2/b_1) + k_3^{-1} \log_{10}(b_3/b_2) + \text{etc.}] \quad \text{(megadarafs per mile)} \quad (122)$$

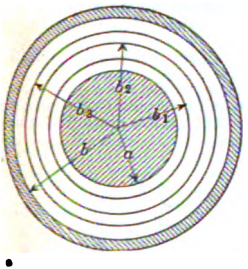

FIG. 17.—Concentric cable.

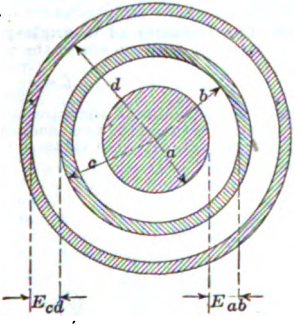

FIG. 18.—Concentric cable and lead sheath.

where $k_1$, $k_2$ . . . are the relative permittivities of the layers (Par. 112). The capacity in microfarads per mile is the reciprocal of this expression. The capacity of a cable is directly proportional to its length, while the elastance is inversely proportional to the length.

**117. For a single-phase concentric cable** with a grounded sheath (Fig. 18), the capacity between two conductors, $C_{ab}$, and that between the outer conductor and the sheathing, $C_{cd}$, is calculated according to the formulæ given above. Then, if the voltage between the two conductors is $E_{ab}$ and the voltage between the outer conductor and the sheathing is $E_{cd}$, the charging current at a frequency of $f$ cycles per second is

$$I = 2\pi f(E_{ab}C_{ab} + E_{cd}C_{cd})10^{-6} \text{ (amp.)}, \quad (123)$$

if $C_{ab}$ and $C_{cd}$ are expressed in microfarads.

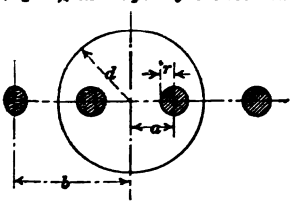

FIG. 19.—Twin conductor cable showing electrical image due to the grounded sheath.

**118. Twin-conductor cable** with grounded sheath. In this case the sheath may be replaced by a pair of conductors located outside, as shown in Fig. 19. The spacing, $b$, of these imaginary conductors being given by the relation*

$$ba = d^2 \quad (124)$$

and the **capacity of a single conductor is**

$$C = \frac{0.03882k}{\log_{10}\left[\frac{2a(d^2-a^2)}{r(d^2+a^2)}\right]} \quad \text{(mf. per mile)}. \quad (125)$$

The capacity per mile of the circuit (two miles of conductor) is one-half

* Leo Lichtenstein. *Elek. Zeit.* Vol. XXV, pp. 106 and 124 (1904).

Digitized by Google

of the preceding value. The transverse dimensions may be either in inches or in centimeters because only their ratio enters in the formula.

**119. A three-conductor cable** may be treated in a similar way (Fig. 20). The sheath is replaced by three equally spaced conductors of the same diameter and spaced according to the relation $ba = d^2$. The **capacity of a single conductor** is

$$C = \frac{0.07764k}{\log_{10}\left[\frac{3a^2(d^2-a^2)^2}{r^2(d^6-a^6)}\right]} \quad \text{(mf. per mile)} \qquad (126)$$

where the transverse dimensions are in inches or in centimeters.

**120. The capacity of a single-phase transmission line** per wire, or the permittance between one of the wires and the plane of symmetry is

$$C = \frac{0.03882}{\log_{10}(b/a)} \quad \text{(mf. per mile)} \qquad (127)$$

where $a$ is the radius of the wire, and $b$ the spacing between the centres. The capacity between the two conductors is equal to one-half of that given by the formula above. For values of charging current at standard frequencies see tables in Sec. 11.

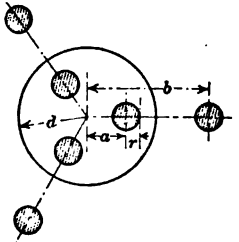

FIG. 20.—Three-conductor cable; showing electrical images due to the grounded sheath.

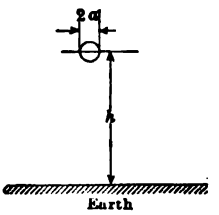

FIG. 21.—Overhead conductor.

**121. The capacity of a single overhead conductor with ground return** (Fig. 21) is

$$C = \frac{0.03882}{\log_{10}(2h/a)} \quad \text{(mf. per mile)} \qquad (128)$$

**122. When a single-phase line with metallic return is suspended sufficiently near the ground** its capacity is somewhat increased. Let the wires be suspended at the heights $h_1$ and $h_2$ above the ground; then calculate the capacity according to formula in Par. **120**, using the corrected spacing (see the author's "Electric Circuit," Art. 61)

$$b_c = \frac{b}{\sqrt{1+(0.25b)^2/h_1h_2}} \qquad (129)$$

When the heights of suspension $h_1$ and $h_2$ are greater than 3.5 times the spacing $b$, the difference between $b$ and the corrected spacing $b_c$ is less than 1 per cent. The correction in formula (117) is still smaller, because logarithms of numbers vary more slowly than the numbers themselves.

In formulæ (128) and (129) a perfectly conducting ground is assumed. With dry non-conducting earth the increase in capacity is somewhat less.

**123. Capacity of a three-phase line with symmetrical spacing.** The concept of the capacity of a three-phase line is not definite without further qualifications. In practice a three-phase line is calculated by reducing it to an equivalent single-phase line consisting of one of the conductors of the three-phase line and a ground return. This equivalent single-phase line carries one-third of the total power transmitted by the three-phase line

Digitized by Google

at a voltage $E/\sqrt{3}$ corresponding to the star voltage of the three-phase line. For such an equivalent line the capacity is expressed by the formula given in Par. **120** above, where $a$ is the radius of each wire and $b$ the spacing between the wires. This expression for capacity means that the charging current per wire calculated from the formula $I = 2\pi fCE/\sqrt{3}$ checks with that actually observed in each wire of a three-phase line when a pure sine-wave voltage $E$ is applied between the wires. For values of charging current see tables in Sec. 11.

**124. With an unsymmetrical spacing** let the actual distances between the three pairs of wires be $b_1$, $b_2$, and $b_3$. The capacity can be calculated from the above given formula using the **equivalent spacing**

$$b_{eq} = \sqrt[3]{b_1 b_2 b_3}, \tag{130}$$

equal to the geometric mean of the actual spacings. For a more detailed treatment of capacity of three-phase lines with unsymmetrical spacing, unsymmetrical voltages and the effect of the ground, see the author's "Electric Circuit," Art. 65. For other formulæ for the capacity of linear conductors and cables see Cohen, L., "Formulæ and Tables for the Calculation of Alternating Current Problems," Chap. 3. See also Fowle, F. F., "The Calculation of Capacity Coefficients for Parallel Suspended Wires," *El. World*, Vol. 58 (1911), pp. 386, 443, and 493.

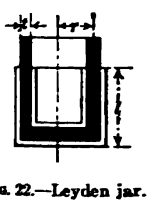

FIG. 22.—Leyden jar.

**125. A Leyden jar** (Fig. 22) may be considered as a combination of plate condensers. Thus, using the general formula Par. **113**, its **capacity**,

$$C = \kappa\frac{A}{t} = \kappa\frac{\pi r^2 + 2\pi rl}{t} \quad \text{(microfarads)} \tag{131}$$

where the dimensions are in centimeters and $\kappa = 0.08842 \times 10^{-6} k$; see Par. **112**.

**126. Permittance of irregular paths.** In some cases it is necessary to calculate the capacity of a condenser the dielectric of which is limited by irregular boundaries. The problem is solved either by experiment or by calculations. In performing the experiment the dielectric is sometimes conveniently replaced by a piece of metal of identical shape and with identical terminals. Let the resistance of the metal paths be $R$, the unknown capacity $C$, the absolute permittivity of the dielectric $k_a$ (Par. **112**) and the resistivity of the metal $\rho$ (Par. **20**). Then

$$C = \frac{k_a}{R}\rho \tag{132}$$

In order to calculate the permittance without any experiment, various assumptions are made as to the most probable paths of the electrostatic lines of force, and of the various assumptions one is selected which gives the maximum permittance. For details see the author's "Electric Circuit," Arts. 54–55.

**127. The energy stored in a condenser.** The potential energy stored in a condenser is

$$W = \frac{CE^2}{2} = \frac{Q^2}{2S} = \frac{EQ}{2}, \quad \text{in joules (watt-seconds)} \tag{133}$$

where the voltage $E$ is in volts, the electrostatic flux (Par. **106**) or charge $Q$ in coulombs, and the capacity $C$ in farads. If $C$ is in microfarads and $Q$ in microcoulombs, $W$ is in microjoules.

**128. The density of electrostatic energy**, or the energy stored per unit volume of the dielectric, is

$$W' = \frac{k_a G^2}{2} = \frac{D^2}{2k_a} = \frac{GD}{2}, \tag{134}$$

where $W'$ is expressed in microjoules per centimeter cube, $k_a$ is the absolute permittivity of the dielectric in microcoulombs per centimeter cube, and $G$ is the voltage gradient in volts per centimeter length of path; $D$ is the dielectric flux density (Par. **107**) in microcoulombs per square centimeter.

The total energy of an electrostatic field is found by multiplying $W'$ by

Digitized by Google

an element of volume $\partial v$ and integrating within the desired limits. For an interesting comparison of practical possibilities as to the amount of energy stored in the dielectric form per unit volume, compared with other forms of energy, see Steinmetz, C. P., *General Electric Review*, 1913, p. 536.

**129. A system of charged bodies** (Fig. 23). The **total charges** on the individual conductors are expressed by the equations

$$\left.\begin{aligned} q_1 &= C_1v_1 + C_{12}(v_1 - v_2) + C_{13}(v_1 - v_3) + \text{ etc.,} \\ q_2 &= C_2v_2 + C_{21}(v_2 - v_1) + C_{23}(v_2 - v_3) + \text{ etc.,} \end{aligned}\right\} \quad (135)$$

where $v_1$, $v_2$, $v_3$, etc., are the potentials of these conductors above the ground. The coefficients $C_1$, $C_2$, $C_3$, etc., are called the **partial capacities** of the conductors; $C_{12}$, $C_{23}$, etc., are called **mutual capacities.** Their computation is possible in a few simple cases only, but having determined them experimentally, it is possible to calculate from the preceding equations the resultant or equivalent capacity of the system under various operating conditions.

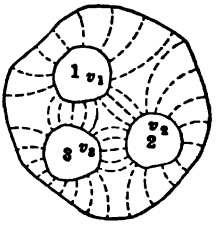

FIG. 23.—System of charged bodies.

**130. Maxwell's equations of a charged system.** The same equation may be written in Maxwell's form

$$\left.\begin{aligned} q_1 &= K_{11}v_1 + K_{12}v_2 + K_{13}v_3 + \text{etc.,} \\ q_2 &= K_{21}v_1 + K_{22}v_2 + K_{23}v_3 + \text{etc.,} \end{aligned}\right\} \quad (136)$$

where the coefficients $K_{11}$, $K_{22}$, etc., are called the capacities of the individual conductors, and the negative quantities $K_{12}$, $K_{23}$, etc., are called **coefficients of mutual induction.**

**131. Coefficients in Maxwell's equations.** The following relations hold between the coefficients $K$ and $C$:

$$\left.\begin{aligned} K_{11} &= C_1 + C_{12} + C_{13} + \text{etc.} \\ K_{22} &= C_2 + C_{21} + C_{23} + \text{etc.} \\ K_{12} &= -C_{12};\ K_{21} = -C_{21}, \text{ etc.} \end{aligned}\right\} \quad (137)$$

**132. The electrostatic energy stored in the field is**

$$W = \tfrac{1}{2}K_{11}v_1^2 + \tfrac{1}{2}K_{22}v_2^2 + \text{etc.} + K_{12}v_1v_2 + K_{13}v_1v_3 + K_{23}v_2v_3 + \text{etc.} \quad (138)$$

$W$ is expressed in joules (watt-seconds) if the potentials are in volts and the capacities in farads.

**133. The dielectric strength of insulating materials, or the rupturing voltage gradient,** is the maximum voltage per unit thickness which a dielectric can stand in a uniform field, before it breaks down electrically. The dielectric strength is usually measured in kilovolts per millimeter or per inch. The only correct way is to refer the dielectric strength to a uniform field, for instance, between large parallel plates placed at a short distance apart. If the striking voltage is determined between two spheres or electrodes of some other shape, the fact should be distinctly stated. In designing insulation a factor of safety is assumed depending upon the conditions of operation. For numerical values of the rupturing voltage gradients of various materials see Sec. 4.

**134. The critical dielectric flux density** is the density at which the material breaks down. It is determined from the relation

$$D_{max} = 0.08842kG_{max} \times 10^{-2}, \quad (139)$$

where $D_{max}$ is the critical density in microcoulombs per square centimeters $G_{max}$ is the **rupturing voltage gradient** in kilovolts per millimeter, and $k$ is the relative permittivity of the material (Par. 112).

**135. Electrostatic corona.** When the electrostatic flux density in the air exceeds a certain value, a pale violet light appears near the adjacent metal surfaces; this silent discharge is called the electrostatic corona. In the regions where the corona appears, the air is electrically broken down, and ionised so that it becomes a conductor of electricity. When the voltage is raised still higher a brush discharge takes place, until the whole thickness of the dielectric is broken down and a disruptive discharge, or spark, jumps from one electrode to the other.

The formation of corona leads to power loss which may be serious in some

Digitized by Google

cases (see Sec. 11). Moreover, corona facilitates the formation of nitric acid near the conductors, and may lead to corrosion. When corona is allowed to play on insulation other than air, this insulation may in time be charred and deteriorated. For these reasons it is of importance to know the critical voltages of corona formation and the power loss under various conditions of surfaces, barometric pressure, humidity, etc. The problem is still in a research state. For numerical data in application to transmission lines see Sec. 11; in connection with the design of other high-tension apparatus, Sec. 10.

**136. Experiments on corona.** A large amount of experimental and theoretical information concerning corona and other allied topics will be found in Vols. XXIX, XXX, and XXXI of the *Trans.* A. I. E. E. See in particular the valuable papers by F. W. Peek, Jr., H. J. Ryan, and J. B. Whitehead, with the accompanying discussion.

**137. Dielectric hysteresis and conductance.** When an alternating voltage is applied at the terminals of a condenser, the dielectric is subjected to periodic stresses and displacements. If the material were perfectly elastic, no energy would be lost during one complete cycle, because the energy stored during the periods of increase in voltage would be given up to the circuit when the voltage decreased. In reality, the electric elasticity of solid and liquid dielectrics is not perfect, so that the applied voltage has to overcome some kind of molecular friction, in addition to the elastic forces. The work done against friction is converted into heat, and is lost, as far as the circuit is concerned. This phenomenon is similar to magnetic hysteresis (Par. 89), and is therefore called *dielectric hysteresis*. The energy lost per cycle is proportional to the square of the applied voltage, because both the displacement and the stress are proportional to the voltage.

An imperfect condenser does not give out on discharge the full amount of energy put into it. After having been discharged and stood some time, an additional discharge may be obtained; this is known as **absorption in the dielectric.**

An imperfect condenser, that is, one which shows a loss of power from one cause or another, can be replaced for purposes of calculation by a perfect condenser with an ohmic conductance shunted around it. This conductance, or "leakance," as some authors call it, is selected of such a value that the $I^2R$ loss in it is equal to the loss of power from all causes in the given imperfect condenser. The actual current through the imperfect condenser is considered then as consisting of two components—the leading reactive component through the ideal condenser, and the loss component, in phase with the voltage, through the shunted conductance. In this way, imperfect condensers can be treated graphically or analytically, according to the ordinary laws of the electric circuit.

## TRANSIENT CURRENTS AND VOLTAGES

**138. Transient electric phenomena** are such as occur between two permanent conditions; for instance, when a load is suddenly changed, an appreciable time elapses before the generators and the line adapt themselves to the new conditions, and the currents and the voltages during the intermediate time are called transient. Some electric phenomena are transient in time (for instance, the short-circuiting of a large alternator), others are transient in space (the distribution of alternating current in solid conductors), and some are transient both in time and in space (surges and traveling waves in long transmission lines).

**139. Theory of transient phenomena.** The subject is too large and advanced to be treated here in detail. An elementary treatment of the subject will be found in W. S. Franklin's "Electric Waves" and in C. P. Steinmetz's "Electric Discharges, Waves and Impulses." Numerous formulæ and results will be found in Cohen's "Formulæ and Tables for the Calculation of Alternating-current Problems," Chaps. 5 and 6. For a more advanced treatment see J. A. Fleming, "The Propagation of Electric Currents;" A. E. Kennelly, "The Application of Hyperbolic Functions to Electrical Engineering Problems," Chap. 6 and foll.; C. P. Steinmetz, "Transient Electric Phenomena and Oscillations." Numerous articles on the subject will be found in the recent volumes of the A. I. E. E., *Elektrotechnische Zeitschrift* and *Archiv für Elektrotechnik*.

**140. Closing a circuit** containing a resistance $r$ (ohms) and an inductance $L$ (henrys) in series with a continuous e.m.f. When the de-energised

Digitized by Google

circuit is suddenly connected to a source of continuous voltage $e$, the current gradually rises to the final value $i_o = e/r$ according to the law

$$i = i_o(1 - \epsilon^{-tr/L}), \tag{140}$$

where $t$ is time, and $\epsilon$ is the base of natural (or hyperbolic) logarithms. This expression is known as **Helmholtz's law.** When the source of e.m.f. is short-circuited the current in the remaining circuit decreases to zero according to a similar law

$$i = i_o\epsilon^{-tr/L}. \tag{141}$$

**141. Periodic e.m.f.** When a de-energized circuit containing $r$ and $L$ is suddenly connected at the instant $t = 0$, to a source of alternating voltage $e = E_m \sin(2\pi ft + \alpha)$, the current in the circuit varies according to the law

$$i = \frac{E_m}{z}\sin(2\pi ft + \alpha - \phi) - \frac{E_m}{z}\sin(\alpha - \phi)\epsilon^{-tr/L} \tag{142}$$

In this equation $z = \sqrt{r^2 + (2\pi fL)^2}$ is the impedance of the circuit and $\phi$ is the phase displacement between the current and the voltage, determined by $\tan\phi = 2\pi fL/r$. The angle $\alpha$ is the phase displacement between the voltage $e$ and the reference wave which passes through zero at the time $t = 0$; $f$ is the frequency. The first term in the expression for $i$ is the current corresponding to the permanent condition, the second term is a transient which rapidly approaches zero with the time. (See also Eq. 146.)

**142. Closing a circuit containing a resistance $r$ (ohms) and a capacity $C$ (farads) in series.** The charging current is theoretically expressed by

$$i = i_o\epsilon^{-t/(rC)}, \tag{143}$$

where $i_o$ is the current at the first instant. This equation is not applicable to the beginning of the charge because it presupposes a sudden jump of the current from zero to $i_o$. In reality, the unavoidable inductance of the circuit smoothes down the initial change in current.

When a condenser, charged at a voltage $e_o$, is discharged through resistance $r$, the discharge current at the first instant is theoretically equal to $i_o = e_o/r$, and then varies according to the law

$$i = i_o\epsilon^{-t/(rC)} \tag{144}$$

The voltage across the condenser terminals decreases according to a similar law

$$e = e_o\epsilon^{-t/(rC)} \tag{145}$$

When a de-energized circuit containing $r$ and $C$ is suddenly connected at the instant $t = 0$ to a source of alternating voltage $e = E_m \sin(2\pi ft + \alpha)$, the current in the circuit will vary according to the law

$$i = \frac{E_m}{z}\sin(2\pi ft + \alpha + \phi) - \frac{E_m}{z}\sin(\alpha + \phi)\epsilon^{-t/(rC)} \tag{146}$$

In this equation $z = \sqrt{r^2 + [1/(2\pi fC)]^2}$ is the impedance of the circuit, and $\phi$ is the phase displacement between the current and the voltage, determined by $\cot\phi = 2\pi fCr$. The angle $\alpha$ is the phase displacement between the voltage $e$ and the reference wave which passes through zero at the time $t = 0$; $f$ is the frequency. The first term in the expression for $i$ is the current corresponding to the permanent condition, the second term is a transient which rapidly approaches zero with the time. Compare Par. **141.**

**143. Single-energy and double-energy transients.** The two preceding cases are examples of single-energy transients, because the energy is stored in one form only (electromagnetic or electrostatic), and the energy change consists in an increase or a decrease of the stored energy. In the case of inductance the energy is that of the magnetic field and in the case of capacity it is the energy of the electrostatic field. When both inductance and capacity are present, the energy of the circuit is stored in two forms, and there is a possibility of periodic transformation of the magnetic energy into the dielectric energy, and *vice versa*, which constitutes electric oscillations, surges, and waves. There is also a possibility of a **triple-energy transient,** when for instance a synchronous motor is hunting at the end of a long transmission line which possesses inductance and capacity. In the last

Digitized by Google

case the total energy of the system is stored not only in the magnetic and the dielectric forms, but in mechanical form as well.

**144. The general differential equation of a circuit containing a resistance r ohms, inductance L henrys and capacity C farads in series,** is

$$L\frac{d^2i}{dt^2}+r\frac{di}{dt}+\frac{1}{C}i=\frac{de}{dt}, \tag{147}$$

where $e$ is the voltage applied to the circuit, and $t$ is time.

When the impressed e.m.f. $e$ is constant ($de/dt=0$), two conditions may arise: $r^2>4L/C$ and $r^2<4L/C$. The intermediate or critical case $r^2=4L/C$ is of academic interest only.

**145. Non-oscillatory case.** In the first case ($r^2>4L/C$) the current in the circuit is non-oscillatory. It rises from zero, reaches a maximum, and falls again to zero when the condenser is fully charged; the current never reverses. The voltage across the condenser gradually rises from zero to its full value, equal to the applied e.m.f., but never exceeding the latter. During the discharge both the current and the voltage across the condenser gradually decrease to zero according to a logarithmic (exponential) law. In practice, these conditions are usually harmless, and therefore desirable in cases where oscillations must be suppressed. This is usually done by increasing the resistance of the circuit until the condition $r^2>4L/C$ is fulfilled.

**146. Oscillatory case.** In the second case, when $r^2<4L/C$, the charge and also the discharge are oscillatory. The oscillations are of decreasing amplitude, because of the damping caused by the energy consumption in the resistance. When the condenser is charging, the current is

$$i=\frac{2e}{q}\,\epsilon^{-rt/2L}\sin\frac{q}{2L}t, \tag{148}$$

and the voltage across the condenser terminals is

$$e_1=e\left\{1-\epsilon^{-rt/2L}\left(\cos\frac{q}{2L}t+\frac{r}{q}\sin\frac{q}{2L}t\right)\right\}. \tag{149}$$

For condenser discharge

$$i=-\frac{2e_o}{q}\epsilon^{-rt/2L}\sin\frac{q}{2L}t, \tag{150}$$

and

$$e_1=e_o\epsilon^{-rt/2L}\left\{\cos\frac{q}{2L}t+\frac{r}{q}\sin\frac{q}{2L}t\right\}. \tag{151}$$

In these expressions $q=\sqrt{(4L/C)-r^2}$; $e$ is the applied voltage, and $e_o$ is the voltage across the condenser at the beginning of the discharge; $\epsilon$ is the base of natural logarithms.

**147. The frequency of oscillation and the logarithmic decrement.** The frequency of oscillations in the preceding case is

$$f=\frac{q}{4\pi L} \qquad \text{(cycles per sec.)} \tag{152}$$

When the resistance is negligible, that is, $r^2$ small compared with $4L/C$, the frequency of oscillations is approximately equal to

$$f_o=\frac{1}{2\pi\sqrt{LC}}. \tag{153}$$

**Logarithmic decrement.** Successive half waves of oscillations decrease the more in amplitude, the greater the resistance. The ratio of the amplitudes of successive half waves, or the decrement of the oscillation, is $\epsilon^{-rt_1/2L}$ where $t_1=1/(2f)$ is the duration of one-half cycle.

**148. Continuous high-frequency oscillations are conveniently produced by use of a direct-current arc** (Duddell). In the Poulsen arc, the anode is copper and the cathode carbon, while the arc is formed in an atmosphere of hydrogen, which appears to increase considerably the intensity of the oscillations. Oscillations have been produced of frequencies ranging as high as one million per second and of considerable power; they are

Digitized by Google

successfully used for wireless telegraphy. See Poulsen, V., "System for Producing Continuous Electric Oscillations," *Trans.* Int. Elec. Congress, St. Louis, 1904, Vol. II, p. 963. Also Austin, L. W., "The Production of High-frequency Oscillations from the Electric Arc," *Bulletin* of the Bureau of Standards, Vol. III (1907), p. 325.

**149. Stored energy.** When a considerable amount of energy is liberated at some point on a transmission line, for instance due to an indirect lightning stroke, a wave starts along the line carrying this energy to the ends of the line. Part of it enters the apparatus at the ends, part is reflected and the rest is converted into heat. Generally speaking, the total energy stored in the line, or in some part of it, at an instant is

$$W = \tfrac{1}{2}Li^2 + \tfrac{1}{2}Ce^2, \qquad \text{(joules)} \qquad (154)$$

where $L$ is the inductance of the line in henrys, $i$ an instantaneous current, $C$ the capacity of the line in farads, and $e$ an instantaneous voltage. The term $\frac{1}{2}Li^2$ represents the electromagnetic energy, the term $\frac{1}{2}Ce^2$ the electrostatic energy. At certain instants the current is equal to zero, at others the voltage is zero, so that the two energies must be equal. Therefore

$$\frac{e_{max}}{i_{max}} = \sqrt{\frac{L}{C}}. \qquad \text{(ohms)} \qquad (155)$$

Thus, knowing the maximum voltage $e_{max}$, the largest instantaneous current $i_{max}$ can be calculated, and *vice versa*. For instance, in the case of a lightning stroke, the maximum voltage is limited by the disruptive strength of the insulation to instantaneous voltages, and the maximum current disturbance may be calculated from the preceding equation.

**150. Surge impedance. With concentrated inductance and capacity, the frequency of oscillations is** (Par. 147)

$$f_o = \frac{1}{2\pi\sqrt{LC}}. \qquad (156)$$

**With uniformly distributed inductance and capacity, the frequency is**

$$f_o' = \frac{1}{4\sqrt{LC}}. \qquad (157)$$

The expression $\sqrt{L/C}$ is called **the natural impedance or the surge impedance of the line,** and its reciprocal **the natural admittance or the surge admittance.** For further information consult the references in Par. 139 above.

## ALTERNATING-CURRENT CIRCUITS

**151. Sine-waves.** In this treatment of alternating-current circuits, a sine-wave is arbitrarily assumed. For non-sinusoidal currents and voltages see Par. 190 and following. Beginning with non-inductive circuits, *i.e.*, circuits which contain only resistance, the current at any instant is proportional to the instantaneous value of the impressed e.m.f. Plotting the instantaneous values of the e.m.f. and the current, it is seen, Fig. 24, that the waves pass through zero and reach their maximum values at the same instant. They are said to be **in phase.**

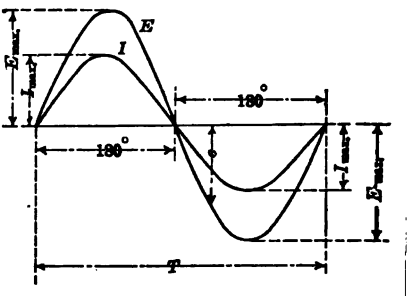

FIG. 24.—Simple sine-waves; non-inductive circuit.

**152. Instantaneous values.** Let the amplitude or the instantaneous maximum value of the voltage be $E_{max}$, then the instantaneous value is

$$e = E_{max} \sin 2\pi ft \qquad (158)$$

where $f$ is the frequency in cycles per second, and $t$ is time in seconds. The angle $2\pi ft$ is in radians. If the time of one complete cycle is $T$ (Fig. 24), $f = 1/T$.

Digitized by Google

**153. Reactive e.m.f.** In a circuit which contains **inductance** only (Par. 67) the current wave lags by 90 electrical degrees, or a quarter of a cycle, behind the applied e.m.f. Numerically

$$E_x = 2\pi f L I \tag{159}$$

where $E_x$ and $I$ are the root-mean-square or the effective values (160) of the voltage and the current respectively, $L$ is the inductance in henrys, and $f$ is the frequency in cycles per second. A similar relation holds true for the amplitudes of voltage and current, or for the average values.

**154. Inductive reactance.** For the sake of abbreviation, the expression $2\pi fL$ is denoted by $x$ and is called inductive reactance, so that

$$x = 2\pi f L = \frac{E_x}{I} \qquad \text{(ohms)} \tag{160}$$

If $L$ is in henrys and $f$ in cycles per second, $x$ is in ohms, being equal to the ratio of the reactive voltage to the current. If the voltage is expressed as in Par. 152, the instantaneous current is

$$i = -\frac{E_{max}}{x} \cos 2\pi f t, \tag{161}$$

in other words, the current wave lags 90 deg. in phase behind the voltage wave.

**155. E.m.f. components. In a circuit which contains resistance and inductance in series,** one portion of the impressed e.m.f. may be considered as consumed in resistance drop and another in the counter-e.m.f. of inductive reactance. The flux interlinked with the circuit is in phase with the current which produces it. The e.m.f. generated in the reactance is proportional to the rate of change of the flux, and since the rate of change of the flux is greatest when the value passes through zero, the e.m.f. is in time-quadrature with the flux and therefore also in time-quadrature with the current (Fig. 25).

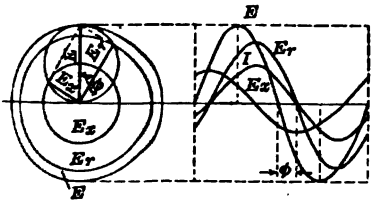

FIG. 25.—E.m.f. and current waves in a circuit containing resistance and reactance in series.

**156. Resultant e.m.f.** The current is always in phase with the e.m.f. which is consumed in resistance, and the impressed e.m.f. is the resultant of the instantaneous values of the components consumed in resistance and in the inductive reactance. Referring to Fig. 25, $E_r$ is consumed in resistance, $E_x$ is consumed in overcoming the counter-e.m.f. of inductive reactance, and $E$ is the resultant or impressed e.m.f.

**157. Phase angle.** The current is in phase with $E_r$ but lags behind the impressed e.m.f. $E$ by the **phase angle** $\phi$ determined from the relation

$$\tan \phi = \frac{2\pi f L}{r} = \frac{x}{r}. \tag{162}$$

If the instantaneous applied voltage is expressed as in Par. 152, the instantaneous current is

$$i = I_{max} \sin(2\pi f t - \phi) \tag{163}$$

where both $2\pi ft$ and $\phi$ are expressed either in radians or in degrees. For the numerical relation between $E$ and $I$ see Par. 165 below.

**158. Capacity reactance or condensance.** In a circuit which contains electrostatic capacity or permittance only, Par. 105, the current wave leads the applied voltage by 90 electrical degrees, or is in leading quadrature with it. Numerically

$$E_c = x_c I \tag{164}$$

where

$$x_c = \frac{1}{2\pi f C} \qquad \text{(ohms)} \tag{165}$$

Digitized by Google

is called capacity reactance, or condensive reactance. When inductive reactance $x$ (Par. **154**) and condensive reactance $x_c$ enter in the same circuit, $x_c$ is considered negative. When $C$ is in farads, $x_c$ is in ohms.

**159. E.m.f. components. In a circuit containing resistance and condensive reactance in series,** the applied e.m.f. may be divided into two components; one consumed in resistance drop and the other in the condensive reactance. The current taken by the condensive reactance is proportional to the rate of change of the e.m.f., which is impressed across its terminals, therefore the counter-e.m.f. of the condensive reactance is in time-quadrature with the current. Referring to Fig. 26, $I$ is the total current in phase with $E_r$ which is the e.m.f. consumed in resistance; $E_r$ is the voltage necessary to balance the counter-e.m.f. of the condensive reactance, and $E$ is the total e.m.f. impressed upon the circuit. It will be seen that in this case the current is leading.

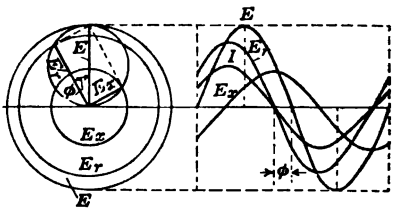

FIG. 26.—E.m.f. and current waves in a circuit containing resistance and capacity reactance in series.

If the instantaneous applied voltage is expressed as in (**152**), the instantaneous current is

$$i = I_{max} \sin (2\pi ft + \phi). \tag{166}$$

In this expression, the **phase angle** $\phi$ between the current and the voltage is determined from the relation

$$\tan \phi = \frac{1}{2\pi fCr} = \frac{x_c}{r}. \tag{167}$$

**160. Terminology.** The following terminology used in application of **sine-wave alternating-current circuits** is recapitulated here for the sake of convenience. An **instantaneous value** of alternating current or voltage (Fig. 24) is connected with the **maximum value** or the **amplitude** by the relation given in Par. **152.** The **mean effective value,** also called the **root-mean-square value,** or simply the **effective value of** an alternating current or voltage is defined in Par. **199.** For a sine-wave quantity the effective value is equal to the amplitude divided by $\sqrt{2}$; or

$$E_{eff} = \frac{E_{max}}{\sqrt{2}} = 0.7071 E_{max}. \tag{168}$$

The **mean or average value** of a sinusoidal alternating current or voltage is equal to the maximum value divided by $\pi/2$, or

$$E_{ave} = \frac{2E_{max}}{\pi} = 0.6366 E_{max}. \tag{169}$$

The ratio between the effective and the average value is called the **form factor** (Par. **207**) and is equal to 1.11 for sine-waves.

**161. Periodic time.** The interval of time $T$ in Fig. 24. corresponds to one complete cycle. The interval of time $T/2$ corresponding to one-half wave is called an **alternation,** and for every cycle there are two alternations. The **frequency** or the **periodicity** of an alternating current may be expressed either in cycles per second or in alternations per minute. However, the latter method is not common.

**162. The phase displacement** between two currents or two voltages, or between a current and a voltage, is commonly measured in **electrical degrees.** One electrical degree is 1/360th part of a complete cycle.

**163. Vector representation.** Alternating currents and voltages which vary according to the sine or cosine law can be represented graphically by directed straight lines called **vectors** (Fig. 27). The length of a vector represents, to some arbitrary scale, the effective value of the alternating

Digitized by Google

quantity, while the position of the vector with respect to a selected reference vector gives the phase displacement. *Counter-clockwise direction of rotation is always considered positive*, so that for instance in the diagram (*b*) the voltage leads the current by 90 deg. By means of vectors the relative phase position and value of either currents or e.m.fs. can be represented in the same manner as forces in mechanics.

**164. Vector diagrams for simple series circuits.** Referring to Fig. 27, diagrams are shown for circuits containing (*a*) resistance; (*b*) inductive reactance; (*c*) condensive reactance; (*d*) resistance and inductive reactance; (*e*) resistance and condensive reactance; (*f*) resistance, inductive reactance and condensive reactance.

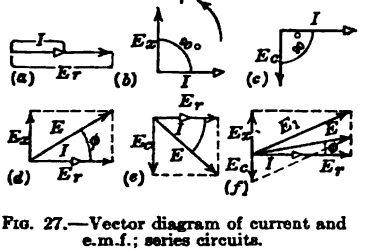

FIG. 27.—Vector diagram of current and e.m.f.; series circuits.

**165. Ohm's law for alternating-current circuits.** The **impedance** (in ohms) is the ratio of an alternating voltage $E$ across a part of a circuit to the current $I$ through the circuit. Denoting the impedance by $z$,

$$E = zI, \qquad (170)$$

where $E$ and $I$ are the effective values. This equation expresses only the numerical relations; it must be remembered that $E$ and $I$ are not in phase with one another.

**166. Impedance consisting of resistance and reactance in series.** In a circuit containing an ohmic resistance $r$ in series with an inductive reactance $x$ (Par. **156**) the impedance is numerically

$$z = \sqrt{r^2 + x^2}, \qquad (171)$$

so that numerically,

$$I = \frac{E}{\sqrt{r^2 + x^2}}. \qquad (172)$$

The **phase angle**, by which the current lags behind the voltage, is found from the relation

$$\tan \phi = \frac{x}{r}, \text{ or } \cos \phi = \frac{r}{z}. \qquad (173)$$

**167. Impedance consisting of resistance and condensance in series.** In a circuit containing an ohmic resistance $r$ in series with a condensive reactance $x_c$ (Par. **159**), similar relations hold, in which $x_c$ is substituted for $x$. The current leads the voltage and the angle $\phi$ is to be considered as negative.

**168. Impedance consisting of resistance, reactance and condensance in series.** If a circuit contain both inductive and condensive reactance (Fig. 27*f*), the impressed e.m.f. is

$$E = \sqrt{E_r^2 + (E_x - E_c)^2} = \sqrt{(Ir)^2 + (Ix - Ix_c)^2}. \qquad (174)$$

Dividing $E$ by $I$, the impedance is

$$z = \sqrt{r^2 + (x - x_c)^2}. \qquad \text{(ohms)} \qquad (175)$$

where

$$x = 2\pi fL = \omega L \qquad \text{(see Par. 154)} \qquad (176)$$

$$x_c = \frac{1}{2\pi fC} = \frac{1}{\omega C} \qquad \text{(see Par. 158)} \qquad (177)$$

**169. Current components; parallel circuits of resistance and reactance.** The current, like the e.m.f., can be split into two components, one in phase and the other in quadrature with the e.m.f. It is convenient to employ the e.m.f. diagram with series circuits and the current diagram with parallel circuits. A current diagram is presented in Fig. 28. It presupposes a non-inductive resistance $r$ connected in parallel with a pure inductive reactance $x$. The total current

$$I = \sqrt{I_r^2 + I_x^2} \qquad \text{(amp.)} \qquad (178)$$

Digitized by Google

If $E$ is the voltage across the circuit, then

$$I_r = E\left(\frac{r}{r^2+x^2}\right) = Eg \quad \text{(amp.)} \quad (179)$$

$$I_x = E\frac{x}{r^2+x^2} = Eb \quad \text{(amp.)} \quad (180)$$

$$I = \sqrt{(Eg)^2+(Eb)^2} = E\frac{1}{z} = Ey \quad \text{(amp.)} \quad (181)$$

In these expressions

$$g = \frac{r}{z^2} = \textbf{conductance} \quad \text{(mho)} \quad (182)$$

$$b = \frac{x}{z^2} = \textbf{susceptance} \quad \text{(mho)} \quad (183)$$

$$y = \frac{1}{z} = \textbf{admittance} \quad \text{(mho)} \quad (184)$$

$$\tan\phi = \frac{I_x}{I_r} = \frac{b}{g};\ \cos\phi = \frac{I_r}{I} = \frac{g}{y}. \quad (185)$$

**170. Resistance and condensance in parallel.** In a circuit consisting of a resistance and a capacity in parallel the same relations hold except that the current is leading, and $x_c$ is used in place of $x$ (Par. **168**). If there is any doubt whether the quadrature current is caused by an inductance or a capacity, use the expressions inductive susceptance and capacity (or condensive) susceptance. The latter is sometimes called **capacitance.** Fig. 28 also shows, in dotted lines, the resultant current when a pure resistance and a pure condensance are connected in parallel; in such case the phase angle $\phi$ becomes an angle of lead.

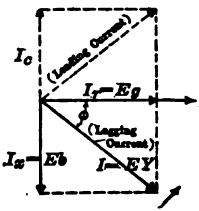

FIG. 28.—Vector diagram of currents; pure resistance in parallel with pure inductive reactance.

**171. Impedances in series.** In a circuit containing several resistances and reactances in series, the resistances should be added together and the reactances added together, so that

$$\left.\begin{aligned} r_{eq} &= \Sigma r; \\ x_{eq} &= \Sigma x; \end{aligned}\right\} \quad (186)$$

$$z_{eq} = \sqrt{(\Sigma r)^2+(\Sigma x)^2}. \quad (187)$$

The subscript *eq* stands for equivalent.

**172. Impedances cannot be added algebraically, but must always be added geometrically,** or vectorially. Since

$$r = z\cos\phi, \text{ and } x = z\sin\phi, \quad (188)$$

the preceding equation gives

$$z_{eq} = \sqrt{(\Sigma z\cos\phi)^2+(\Sigma z\sin\phi)^2}. \quad (189)$$

**173. Admittances in parallel.** In a circuit consisting of several parallel branches the conductances should be added together and the susceptances added together (Par. **169**) so that,

$$\left.\begin{aligned} g_{eq} &= \Sigma g \\ b_{eq} &= \Sigma b \end{aligned}\right\} \quad (190)$$

and

$$y_{eq} = \sqrt{(\Sigma g)^2+(\Sigma b)^2}. \quad (191)$$

**174. Admittances cannot be added algebraically, but must always be added geometrically,** or vectorially. Since

$$g = y\cos\phi, \text{ and } b = y\sin\phi, \quad (192)$$

the preceding equation gives

$$y_{eq} = \sqrt{(\Sigma y\cos\phi)^2+(\Sigma y\sin\phi)^2}. \quad (193)$$

**175. Equivalent series and parallel combinations.** Let $r_s$ and $x_s$ be a resistance and a reactance connected in series and let $r_p$ and $x_p$ be a

Digitized by Google

resistance and a reactance connected in parallel. The two combinations are called equivalent when a given impressed alternating voltage produces the same total current through both, in magnitude and in phase. In other words, both combinations must have the same impedance $z$ (or admittance $y$), and the same phase angle $\phi$. The two resistances and the two reactances are connected by the relations

$$\left.\begin{aligned} r_s r_p &= z^2 = \frac{1}{y^2}, \\ x_s x_p &= z^2 = \frac{1}{y^2}; \end{aligned}\right\}$$

and also

$$\left.\begin{aligned} g &= \frac{r_s}{z^2}, \quad b = \frac{x_s}{z^2}, \\ r_s &= \frac{g}{y^2}, \quad x_s = \frac{b}{y^2}. \end{aligned}\right\} \tag{194}$$

**176. Calculation of series-parallel circuits.** The foregoing relations are useful in determining the voltage and current relations obtaining in complex series-parallel circuits. For example, in the circuit shown in Fig. 29 the resistance $r^1$ in series with reactance $x_1$ is replaced by a conductance $g_1 = r_1/z_1^2$ in parallel with a susceptance $b_1 = x_1/z_1^2$, where

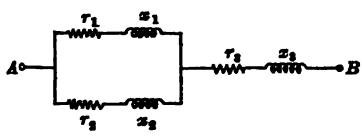

FIG. 29.—Series-parallel combination.

$$z_1^2 = r_1^2 + x_1^2. \tag{195}$$

A similar substitution is made for the branch 2, then the branches 1 and 2 are replaced by one equivalent branch of conductance $g_4 = g_1 + g_2$ in parallel with the susceptance $b_4 = b_1 + b_2$. Now the branch $g_4$, $b_4$, is replaced by an equivalent series combination consisting of a resistance $r_4 = g_4/y_4^2$ in series with a reactance $x_4 = b_4/y_4^2$, where

$$y_4^2 = g_4^2 + b_4^2. \tag{196}$$

The original series-parallel combination is thus reduced to a simple series circuit, and we finally have

$$\left.\begin{aligned} r_{eq} &= r_3 + r_4, \\ x_{eq} &= x_3 + x_4. \end{aligned}\right\} \tag{197}$$

Knowing $r_{eq}$ and $x_{eq}$ the total current may be found for a given voltage or *vice versa*, from the relations given in Par. 166.

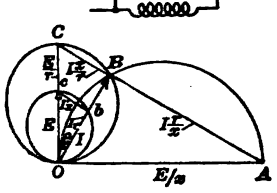

FIG. 30.—Circle diagram for series circuits.

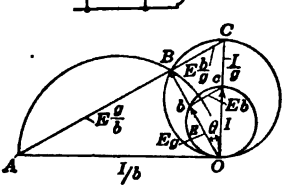

FIG. 31.—Circle diagram for parallel circuits.

**177. Circle diagram; series circuits.** Drs. F. Bedell and A. C. Crehore developed a circle diagram which shows the interrelation of the various constants in an alternating-current circuit when one or more quantities are varied.

Digitized by Google

Considering the series circuit shown in Fig. 30, let it be required to study the current when the resistance and reactance are varied, the e.m.f. being kept constant. With $E$ as a diameter draw the circle. *Obc*, then *Obc* is the e.m.f. or impedance triangle and $\theta$ is the angle of phase displacement between $I$ and $E$. Dividing the current, $I$, into imaginary components, $E/r$ is laid off along $OC$ in phase with $E$, and $E/x$ is laid off along $OA$ in quadrature with $E$. Drawing the line $AC$, and the circles, $OBA$ and $OBC$, the line, $OB$, represents the current, $I$, both as to value and phase position. If $x$ is constant and $r$ variable, the point, $B$, will travel along the circle, $OBA$, while if $r$ is constant and $x$ variable, the point, $B$, will travel along the circle, $OBC$.

**178. Circle diagram; parallel circuits.** Referring to the parallel circuit in Fig. 31, let it be required to study the e.m.f. when the conductance and susceptance are varied, the current remaining constant. With $I$ as diameter draw the circle *Obc*, then *Obc* is the current or admittance triangle and $\theta$ is the angle of phase displacement between $E$ and $I$. Dividing the e.m.f. into components, $I/b$ is laid off along $OA$ in quadrature with $I$; then drawing the line, $AC$, and the circles, $OBA$ and $OBC$, the line, $OB$, represents the e.m.f., $E$, both as to value and phase position. The circle, $OBA$, is the locus of the point, $B$, when $b$ is constant and $g$ variable, while the circle, $OBC$, is the locus of the point, $B$, when $g$ is constant and $b$ variable.

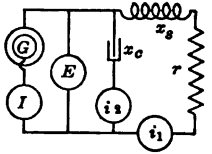

FIG. 32.—Condensance in parallel with inductive impedance.

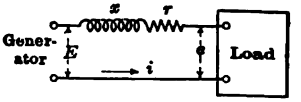

FIG. 33.—Load connected to inductive line.

**179. Phase compensation. Condensive reactance** connected **in shunt with an inductive impedance** can be so adjusted as to bring the total current more or less in phase with the impressed e.m.f. Referring to Fig. 32, $x_c$ and the impedance $z_s$ are in parallel, where

$$z_s^2 = r^2 + x_s^2. \tag{198}$$

Taking the admittances,

$$g_1 = \frac{r}{z_s^2}; \; g_2 = 0; \; b_1 = \frac{x_s}{z_s^2}; \text{ and } b_2 = -\frac{1}{x_c}. \tag{199}$$

In order that $I$ be in phase with $E$, $b_1 + b_2$ must be equal to zero, or

$$x_c = \frac{z_s^2}{x_s}. \tag{200}$$

Thus, it is seen that the value of $x_c$ depends upon the resistance, r, as well as upon $x_s$:

$$i_2 = E\frac{1}{x_c} = Eb_2; \; i_1 = E\sqrt{\left(\frac{r}{z_s^2}\right)^2 + \left(\frac{x_s}{z_s^2}\right)^2} = E\sqrt{g_1^2 + b_1^2}, \tag{201}$$

$$I = E\sqrt{\left(\frac{r}{r^2+x_s^2}\right)^2 + \left\{\left(\frac{x_s}{r^2+x_s^2}\right) - \frac{1}{x_c}\right\}^2} = E\sqrt{g^2+b^2}, \text{ in amp.} \tag{202}$$

**180. Leading current through an inductive line** will raise the e.m.f. at the receiving end of the circuit. Referring to Fig. 33, let $E$ be the voltage at the generator end of a circuit, $e$ the voltage at the receiver end, and $i$ the line current. Let the load be of such a nature that the current is leading with respect to the voltage $e$. Adding to $e$ the ohmic drop $ir$ in the line (Fig. 34*a*) in phase with $i$, and the reactive drop $ix$ in leading quadrature with $i$, the impressed voltage $E$ is obtained. It will be seen that $E < e$; but with a lagging current, $E > e$ (Fig. 34*b*).

**181. Series resonance.** In a constant-potential circuit which contains inductive reactance and also condensive reactance in series, it is possible

Digitized by Google

to obtain an enormous rise in e.m.f. by adjusting the reactances or the frequency. Thus, according to Par. 168,

$$E = Iz = I\sqrt{r^2+(x_s-x_c)^2}, \qquad \text{(volts)} \qquad (203)$$

The e.m.f. across the condensive reactance is

$$e = Ix_c,$$

so that

$$\frac{e}{E} = \frac{x_c}{\sqrt{r^2+(x_s-x_c)^2}} = \frac{x_c}{z}. \qquad (204)$$

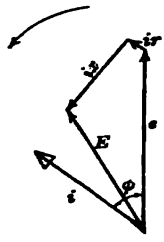

FIG. 34a.—Effect of inductance with leading current.

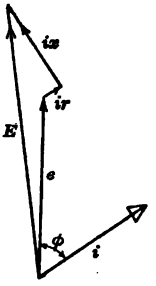

FIG. 34b.—Effect of inductance with lagging current.

Now, $z$ (the total impedance) may be less than $x_s$, and in this case $e$ (the drop across the condenser terminals) will be greater than $E$ (the total impressed e.m.f.). If the frequency is

$$f = \frac{1}{2\pi\sqrt{LC}}, \qquad \text{(cycles per second)} \qquad (205)$$

we shall have

$$x_s = x_c, \qquad (206)$$

which conditions gives the highest rise in voltage. If moreover $r$ (the resistance of the circuit) is assumed to be zero,

$$\frac{e}{E} = \infty, \qquad (207)$$

and we have an extreme case of **voltage resonance.**

This is purely an ideal case, but in any event

$$\frac{e}{E} = \frac{x_c}{r} \text{ when } f = \frac{1}{2\pi\sqrt{LC}}; \qquad (208)$$

wherein $L$ is the coefficient of self-induction in henrys and $C$ the capacity in farads of the apparatus connected in series. Sometimes the constants of the circuit are such that a resonance of one of the higher harmonics of the voltage takes place.

**182. Parallel resonance.** When an inductive reactance and a condensive reactance are joined together in parallel, they can be so adjusted or the frequency can be so chosen that **current resonance** will take place.

Let the total conductance of the combination be $g$, the inductive susceptance $b_s$ and the condensive susceptance $b_c$. Then, the total current

$$I = Ey = \sqrt{g^2+(b_s-b_c)^2} \qquad (209)$$

The current through the condensive susceptance is

$$i_c = Eb_c, \qquad (210)$$

so that

$$\frac{i_c}{I} = \frac{b_c}{\sqrt{g^2+(b_s-b_c)^2}} = \frac{b_c}{y}. \qquad (211)$$

Digitized by Google

But the total admittance $y$ may be smaller than $b_o$, and in this case the total line current $I$ is less than one of its components $i_o$. A similar relation may be proved for $i_s$. When the frequency is

$$f = \frac{1}{2\pi\sqrt{LC}}, \quad \text{(cycles per second)} \tag{212}$$

it follows that

$$b_s = b_o, \tag{213}$$

and

$$I = Eg, \quad i_s = -i_o. \tag{214}$$

The line current is comparatively small, but there is a large interchange of current between the inductance and the capacity, in parallel.

**Resonance can occur at only one frequency.** Sometimes, in the case of a complex wave, it occurs at the frequency of one of the component harmonics instead of the fundamental frequency. In such case, either for voltage or current (series or parallel resonance), the magnitude of the resonant harmonic component is much exaggerated, as compared with its normal magnitude in a non-resonant circuit. The condition of resonance, except in tuned circuits where it is specially desired (as in radio-telegraphy), is one to be avoided.

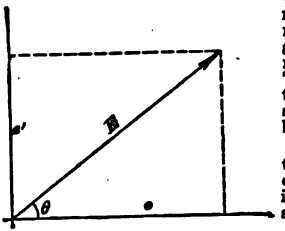

FIG. 35.—Complex quantities; axes of reals and imaginaries.

**183. Consonance.** Resonance in the primary circuit of a transformer, caused by the proper combination of inductance and capacity in the secondary circuit, is called consonance.

**184. Alternating currents and voltages treated by means of complex (imaginary) quantities.** If $e$ and $e'$ (Fig. 35) are the projections or the components of a vector $E$ along two perpendicular axes, then the vector $E$ may be represented symbolically as

$$\dot{E} = e + je', \tag{215}$$

where

$$j = \sqrt{-1}, \tag{216}$$

and the dot under $E$ signifies that the magnitude as well as the direction of $E$ is meant.

**185. Addition and subtraction of vectors.** Let two vectors of voltage be represented as

$$\dot{E}_1 = e_1 + je'_1, \tag{217}$$

$$\dot{E}_2 = e_2 + je'_2. \tag{218}$$

Then the sum or the difference of these two vectors is

$$\dot{E}_3 = \dot{E}_1 \pm \dot{E}_2 = (e_1 \pm e_2) + j(e'_1 \pm e'_2). \tag{219}$$

**186. Rotation of a Vector.** Multiplying a vector by $j$ turns it by 90 deg. in the positive direction (counter-clockwise). Thus,

$$j\dot{E} = j(e + je') = -e' + je, \tag{220}$$

because $j^2 = -1$. Multiplying a vector by $-j$ rotates the vector by 90 deg. in the negative direction—that is, clockwise.

A vector $\dot{E}$ may be also represented symbolically (Fig. 35) as

$$\dot{E} = E(\cos\theta + j\sin\theta), \tag{221}$$

where $E$ without the dot, on the right-hand side of the equation, stands for the magnitude only.

The operator

$$e^{j\phi} = \cos\phi + j\sin\phi, \tag{222}$$

where $e$ is the base of natural logarithms, turns a vector by the angle $\phi$ in the positive direction. Thus,

$$\dot{E}(\cos\phi + j\sin\phi) = E(\cos\theta + j\sin\theta)(\cos\phi + j\sin\phi) = E[\cos(\theta+\phi) + j\sin(\theta+\phi)]. \tag{223}$$

Digitized by Google

The operator

$$\epsilon^{-j\phi} = \cos\phi - j\sin\phi \tag{224}$$

turns a vector by the angle $\phi$ in the negative direction, that is, clockwise.

**187. Impedance and admittance operators. The impedance operator**

$$Z = r + jx \tag{225}$$

converts the vector of a current into that of a potential difference across an impedance (consisting of a resistance $r$ in series with a reactance $x$). **The admittance operator**

$$Y = g - jb \tag{226}$$

converts the vector of a voltage applied across the terminals of a conductance $g$ in parallel with a susceptance $b$, into the vector of the total current through this combination. Thus, if a current $\dot{I} = i + ji'$ flows through the impedance $Z = r + jx$, the required voltage is

$$\dot{E} = Z\dot{I} = (r + jx)(i + ji'), \tag{227}$$

or, separating the real and the imaginary quantities,

$$\dot{E} = (ir - i'x) + j(i'r + ix). \tag{228}$$

In other words, $\dot{E}$ is a vector such that its horizontal projection $e$ (Fig. 35) is equal to $(ir - i'x)$, and the vertical projection is $(i'r + ix)$.

The angle $\theta$ which the vector $\dot{E}$ forms with the horizontal axis is determined by

$$\tan\theta = \frac{(i'r + ix)}{(ir - i'x)}. \tag{229}$$

**188. Networks of conductors.** The method given in Par. **29** to **35** is generalized in the case of alternating e.m.fs. by writing Kirchhoff's equations for the vectors of the currents and of the voltages. With the notation used above, we have

$$\Sigma\dot{I} = 0; \quad \Sigma\dot{E} = \Sigma\dot{I}Z. \tag{230}$$

Equating the vertical and the horizontal projections of the vectors to zero separately (Fig. 35), and using expression (228), equations (230) become

$$\left.\begin{array}{l} \Sigma i = 0; \ \Sigma i' = 0; \\ \Sigma(ir - i'x) = \Sigma e; \\ \Sigma(i'r + ix) = \Sigma e'. \end{array}\right\} \tag{231}$$

If there are $n$ unknown currents or voltages, $2n$ independent equations of the form (231) may be written, and from these equations $2n$ projections of $n$ unknown vectors can be determined. The problem is thus similar to that with direct currents, and the references given in Par. **35** may be consulted for simplifications which may be taken advantage of in practical cases.*

**189. The expressions for power and power factor.** The average power expressed through the projections of the vectors is

$$P = ei + e'i' = EI\cos\phi, \tag{232}$$

where $e$ and $e'$ are the projections of the voltage $\dot{E}$ (Fig. 35), and $i$ and $i'$ are those of the current $I$. Note that the power is not a vector quantity.

The power factor is found from the relation

$$\cos\phi = \cos(\theta_e - \theta_i), \tag{233}$$

where

$$\theta_e = \tan^{-1} e'/e \text{ and } \theta_i = \tan^{-1} i'/i. \tag{234}$$

Or else, the angle $\phi$ is found directly from the relation

$$\tan\phi = [(e'/e) - (i'/i)]/[1 + (e'i'/ei)] \tag{235}$$

If $\tan\phi$ is positive, the current is lagging; otherwise it is leading—with respect to the e.m.f. See also Par. **196**.

## NON-SINUSOIDAL OR COMPLEX WAVES

**190. Examples of complex waves.** The curves shown in Fig. 36 illustrate the effect of the inductance and the capacity in a circuit to which is applied an alternating e.m.f., differing from the simple sine-wave. The curves were taken simultaneously with an oscillograph. $E$ is the impressed e.m.f.; $I_s$ the current taken by an inductance coil, and $I_c$ that taken by a condenser. Fig. 37 shows the circuit.

**191. Wave of reactive e.m.f. due to inductive reactance.** Assuming the reluctance of the iron core in the inductance coil to be constant, which is approximately true below the saturation point, the value of

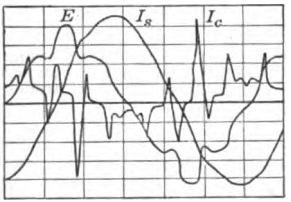

FIG. 36.—Complex alternating-current waves.

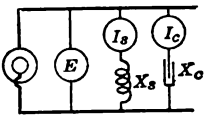

FIG. 37.—Circuit in which the waves of Fig. 36 were observed.

the flux is proportional to the current $I_s$. The instantaneous value of the e.m.f. $E$ (see Par. **67**) is

$$e = n\frac{d\phi}{dt} = L\frac{di}{dt} \tag{236}$$

that is, the curve $E$ will have its maximum amplitude when the curve $I_s$ passes through zero. This is not exactly true in this case, because of a small loss in the resistance and the iron; the current to supply this loss being in phase with the e.m.f. $E$.

**192. Wave of current through condensive reactance.** The condenser current is proportional to the rate of change of the e.m.f. (see Par. **108**); the instantaneous value is

$$i_c = C\frac{de}{dt}, \tag{237}$$

that is, the curve, $I_c$, has its maximum when the rate of change of the curve, $E$, is a maximum. Were $E$ a sine curve, $I$ would be also a sine curve and would be in quadrature with $E$, but when the curve of e.m.f. is not a sine curve, as in Fig. 36, the maximum amplitude of the current will occur at the point where the slope of the e.m.f. curve is a maximum.

**193. Effects of inductive and condensive reactance on wave form.** These curves show the effect upon the current wave form of inductive reactance and condensive reactance. The curve, $E$, is the wave form produced by the generator; it contains several harmonics (see Par. **209**). The inductive reactance tends to damp out the higher harmonics, while the condensive reactance emphasizes them.

**194. Determination of total complex current wave.** When the applied voltage contains higher harmonics (Par. **209**) the total current through an impedance is found by summing the harmonic currents due to each harmonic of the voltage acting alone. Thus, the reactance at the fundamental frequency $f$ is $x_1 = 2\pi fL$, the reactance to the $n$th harmonic is $x_n = 2\pi nfL$, and the impedance to the $n$th harmonic is

$$z_n = \sqrt{r^2 + (2\pi nfL)^2}. \tag{238}$$

**195. Power and energy.** The general expression for the energy delivered to an alternating-current circuit with any wave form of current and voltage is

$$W = \int_{t_1}^{t_2} eidt \text{ (joules or watt-seconds)}, \tag{239}$$

Digitized by Google

where $e$ is an instantaneous value of the voltage in volts, $i$ is the corresponding instantaneous current in amperes and $t_2 - t_1 = T$ is the interval of time, in seconds, for which the energy is to be determined. The average power delivered during the same interval is

$$P = \frac{1}{t_2 - t_1} \int_{t_1}^{t_2} ei\,dt \qquad \text{(watts)} \qquad (240)$$

**196. Power factor, sine-waves.** When the current and the voltage vary according to the sine law, the power $P = IE \cos \phi$, where $E$ and $I$ are the effective values of the voltage and the current respectively, and $\phi$ is the phase angle between the two, $\cos \phi$ being known as the power factor of the circuit. See also Par. **189**.

**197. Power factor, complex waves.** When $e$ and $i$ are irregular curves, the average power is found as the average ordinate of a curve, the ordinates of which are proportional to the product $ei$. If $e$ and $i$ are resolved into their harmonics, each harmonic contributes its own share of power as if it were acting alone, so that the average power is

$$P = E_1 I_1 \cos \phi_1 + E_2 I_2 \cos \phi_2 + \text{etc.}, \qquad (241)$$

where $I_1$, $I_2$, etc., and $E_1$, $E_2$, etc., are the effective values of the harmonic currents and voltages respectively, and the angles $\phi$ are the respective phase displacements.

**198. The energy component and the reactive component of voltage or current.** In a simple harmonic circuit with the voltage $E$, current $I$, and the phase displacement $\phi$ between the two, $E \cos \phi$ is called the energy component of the voltage and $E \sin \phi$ the reactive component of the voltage. Analogously, $I \cos \phi$ is the energy component of the current and $I \sin \phi$ is the reactive component of the current. Similar components are used in circuits with non-sinusoidal currents and voltages, provided that these are first replaced by equivalent sine-waves.

**199. Effective value of any wave.** The effective value of a variable current or voltage is defined as that continuous value which gives the same total $i^2r$ loss. Or, if $I$ be the effective value of a variable current $i$,

$$\left.\begin{aligned} I^2rT &= \int_0^T i^2r\,dt \qquad \text{(joules)} \\ \text{from which} \qquad I &= \sqrt{\frac{1}{T}\int_0^T i^2\,dt} \qquad \text{(amp.)} \end{aligned}\right\} \qquad (242)$$

This may be expressed by saying that the *effective value of a current or voltage is equal to the square root of the mean square (r.m.s.) of the variable values.* Hot-wire instruments and electrodynamometer-type instruments indicate directly the effective values of alternating currents and voltages.

**200. Effective value of a sine-wave.** For sine-waves the effective values are given in Par **160**. In terms of the maximum value, the effective value is $E_{eff} = 0.7071\ E_{max}$.

**201. Computation of effective value of a complex wave; first method.** For irregular waves the following **four methods** are used in order to obtain the effective value of the ordinates of a curve, $y = f(x)$. Under the first method, plot a curve the ordinates of which are equal to $y^2$. Determine the average ordinate of this curve either by a planimeter or by weighing the paper on which it is drawn, and take the square root of the value of this ordinate.

**202. Second method.** According to **Simpson's rule,*** divide the curve

* Simpson's Rule is a formula for computing the area comprised between a given curve, $y = f(x)$, the axis of abscissæ and two given ordinates. Divide the distance between the given ordinates into $n$ equal parts, where $n$ is an even number, and erect the corresponding ordinates. Let these ordinates,

Digitized by Google

into $k$ equal parts by $k+1$ equidistant ordinates $y_0$, $y_1$, etc., $y_k$, where $k$ is an even number. Then the effective value is

$$y_{eff} = \frac{1}{\sqrt{3k}}\left[ y_0^2+4(y_1^2+y_3^2+\text{etc.}+y_{k-1}^2)+2(y_2^2+y_4^2+etc+y_{k-2}^2)+y_k^2\right]^{\frac{1}{2}}. \tag{243}$$

**203. Third method.** If the irregular wave is given in terms of its harmonics, then the effective value is

$$y_{eff} = 0.7071\sqrt{A_1^2+A_3^2+\text{etc.}}, \tag{244}$$

where $A_1$, $A_3$, etc., are the amplitudes of the separate harmonics.

**204. Fourth method.** Replot the given irregular curve (Fig. 38) in polar coordinates (Fig. 39), and determine the area $A_p$, of the polar curve, with a planimeter, or by plotting on homogeneous paper of known area and weight, then cutting out and weighing again; the areas are then proportional

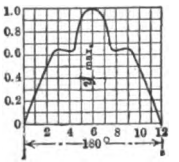

FIG. 38.—Complex wave in rectangular coordinates.

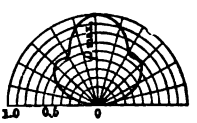

FIG. 39.—Complex wave of Fig. 38 in polar coordinates.

to the weights. This area must be expressed in units, $y^2_{max}$, as taken from Fig. 38. This is done by multiplying the area, $A_p$, of the polar curve by the ratio $\left(\frac{y_{max}}{\rho_{max}}\right)^2$; $y_{max}$ and $\rho_{max}$ are measured in terms of the same units.

The mean effective ordinate is

$$y_{eff} = \frac{y_{max}}{\rho_{max}}\sqrt{\frac{2A_p}{\pi}}, \qquad \text{in terms of } y_{max}. \tag{245}$$

**205. Generalization of fourth method.** The latter method has been generalized by Mr. C. O. Mailloux for determining the effective value of direct current taken by an electric car or a train during a run. For a detailed treatment and numerous practical applications see his paper "Methode de Determination du Courant Constant Produisant le Même Echauffement qu'un Courant Variable," in the Transactions of the International Electrical Congress held at Turin (Italy), 1911.

**206. The amplitude factor** is the ratio of the maximum ordinate to the mean effective ordinate, thus

$$\frac{y_{max}}{y_{eff}} = \text{amplitude factor}. \tag{246}$$

**207. The form factor** is the ratio of the mean effective ordinate to the mean ordinate, thus

$$\frac{y_{eff}}{y_{mean}} = \text{form factor}. \tag{247}$$

---

including the two given ones, be denoted $y_0$, $y_1$, $y_2$, etc., $y_n$. Then the area of the curve is

$$A = \tfrac{1}{3}h[y_0+4(y_1+y_3+y_5+\text{etc.}+y_{n-1})+2(y_2+y_4+y_6+\text{etc.}+y_{n-2})+y_n],$$

where $h$ is the distance between any two adjacent ordinates. The greater the number of strips ($n$), the more nearly the foregoing formula represents the area of the given curve.

Digitized by Google

The table in Par. **208** gives the form factor and the amplitude factor for various mathematical curves.

**208. Table of Form Factors and Amplitude Factors.**

| Name. | Trace. | Form factor. | Reciprocal of form factor. | Amplitude factor. | Reciprocal of amplitude factor. |
|---|---|---|---|---|---|
| Rectangle | | 1.00 | 1.00 | 1.00 | 1.00 |
| Semi-ellipse | | 1.04 | 0.96 | 1.22 | 0.82 |
| Semi-circle | | 1.04 | 0.96 | 1.22 | 0.82 |
| Semi-ellipse | | 1.04 | 0.96 | 1.22 | 0.82 |
| Sine | | 1.111 | 0.900 | 1.414 | 0.707 |
| Triangle | | 1.15 | 0.87 | 1.73 | 0.58 |
| Inverse sine | | 1.31 | 0.76 | 2.10 | 0.48 |
| Inverse circle or inverse ellipse | | 1.44 | 0.69 | 3.23 | 0.31 |

**209. Wave analysis; Fourier's series.** In the mathematical treatment of alternating waves, it is most convenient to work with those having sine form; therefore, *those waves differing from the sine form are generally resolved into both a fundamental sine-wave and its harmonics.* The general equation of any alternating wave, as given by Fourier's series, is

$$y = Y_1 \sin(\omega + \theta_1) + Y_2 \sin(2\omega + \theta_2) + \ldots + Y_n \sin(n\omega + \theta_n) + \text{etc.}, \quad (248)$$

wherein $y$ is the ordinate of the resultant wave; $Y_1$, $Y_2$, . . . $Y_n$, etc., are the maximum ordinates of the first, second, . . . $n$th, etc., harmonics; $\theta_1$, $\theta_2$, . . . $\theta_n$, the constant angles which determine the relative time-phase position of the corresponding harmonics, and $\omega = 2\pi f$ the angular velocity of the generating vector of the fundamental wave.

**210. Wave analysis; Fischer-Hinnen's method.** By inspection it can be said that waves having like loops above and below the time axis contain only odd harmonics, while waves having unlike loops above and below the axis contain both even and odd harmonics. A direct method of wave analysis given by J. Fischer-Hinnen* is based on the following equations:

$$A_n = \frac{1}{n}(y_4 + y_8 + y_{12} + \ldots y_{2n-2} - y_2 - y_6 - y_{10} - \ldots y_{2n-4}) \quad (249)$$

and

$$B_n = \frac{1}{n}(y_1 + y_5 + y_9 + \ldots y_{2n-1} - y_3 - y_7 - y_{11} - \ldots y_{2n-3}) \quad (250)$$

wherein $y_1$, $y_2$ . . . $y_n$ are ordinates at points along the base of the half wave, which is divided into $2n$ equal parts, and $A_n$ and $B_n$ are the ordinates of the $n$th harmonics lying 90 time-degrees apart. The maximum ordinate of the $n$th harmonic is $\sqrt{A_n^2 + B_n^2}$, and its time phase displacement from the resultant wave is

$$\theta_n = \tan^{-1}\left(\frac{A_n}{-B_n}\right), \quad (251)$$

* *Elek. Zeit.*, Vol. XXII, p. 396 (1901). Also P. M. Lincoln, *Elec. Jour.*, Vol. V, p. 286 (1908).

Digitized by Google

$\theta_n$ being measured in terms of the $n$th harmonic. Assuming time measured to the right and ordinates measured up as positive, and quantities measured in opposite directions as negative, positive values of $\theta_n$ indicate that the nearest intersection of the $n$th harmonic with the axis is to the right of the intersection of the resultant wave with the axis, and positive values of $B_n$ indicate that the $n$th harmonic is rising at its nearest intersection with the time axis. The values obtained with the above equations for the $n$th harmonic are affected by the harmonics which are multiples thereof, that is $2n$, $3n$, etc. This correction is practically negligible for all harmonics, except the first or fundamental, and a correction rarely needs to be carried beyond the ninth harmonic. Since wave forms in practice almost never contain even harmonics, they do not enter into the correction, and denoting the corrected values by prime, we have:

$$A'_n = A_n - A'_{3n} - A'_{5n} - A'_{7n} - \quad . \quad . \quad . \tag{252}$$

and

$$B'_n = B_n + B'_{3n} - B'_{5n} + B'_{7n} - \quad . \quad . \quad . \tag{253}$$

When applying this to the first harmonic, $A_n$ is the ordinate of the resultant wave at $y_0$ (Fig. 40b), and $B_n$ is the ordinate 90 time-degrees therefrom at $y_3$.

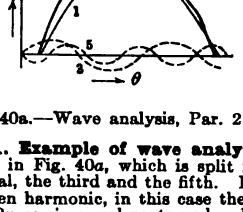

FIG. 40a.—Wave analysis, Par. 211.

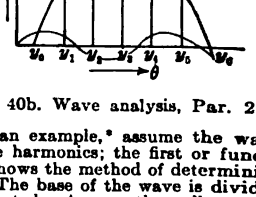

FIG. 40b. Wave analysis, Par. 211.

**211. Example of wave analysis.** As an example,* assume the wave given in Fig. 40*a*, which is split into three harmonics; the first or fundamental, the third and the fifth. Fig. 40*b* shows the method of determining a given harmonic, in this case the third. The base of the wave is divided into $2n$ or six equal parts and ordinates erected. Assume the ordinates to measure as follows:

$$y_1 = 676;\ y_2 = 660;\ y_3 = 940;\ y_4 = 1004;\ y_5 = 554;\ y_6 = 0. \tag{254}$$

then,

$$A_3 = \tfrac{1}{3}(y_4 - y_2) = \frac{1004 - 660}{3} = 114.7, \tag{255}$$

and

$$B_3 = \tfrac{1}{3}(y_1 + y_5 - y_3) = \frac{676 + 554 - 940}{3} = 96.7. \tag{256}$$

The maximum ordinate is

$$\sqrt{(114.7)^2 + (96.7)^2} = 150 \tag{257}$$

and the phase angle is

$$\theta_3 = \tan^{-1}\left(\frac{-114.7}{96.7}\right) = -50 \text{ deg.}\dagger \tag{258}$$

In a similar manner it is found that $A_5 = -92.8$, and $B_5 = 37.4$. In this example the wave contains only the third and the fifth harmonics; therefore, the fundamental is determined as follows:

$$A_1 = y_0 - A'_3 - A'_5 = 0 - 114.7 + 92.8 = -21.9;$$
$$B_1 = y_3 + B'_3 - B'_5 = 940 + 96.7 - 37.4 = 999.3;$$
$$\theta_1 = \tan^{-1}(21.9/999.3) = 1 \text{ deg. } 15 \text{ min. (approx.)}$$

* *Elec. Jour.*, Vol. V, p. 386 (1908).

† Fifty deg. in the terms of the third harmonic, or 50/3 deg. in terms of the resultant

**212. Wave analysis tables** are available (Published by John Wiley and Sons, Inc.,) by means of which an irregular wave may be easily analyzed into its harmonics by taking a sufficient number of ordinates. For the use of these tables see the author's "Experimental Electrical Engineering," Volume II, Chapter 31; John Wiley and Sons, New York, 1911.

## POLYPHASE SYSTEMS

**213. A polyphase system** is an alternating-current circuit or network to which are applied two or more e.m.fs. of the same frequency, but displaced in phase by a fixed amount relatively to one another.

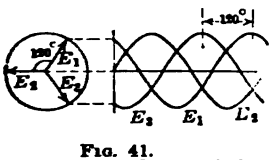

FIG. 41.

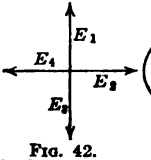

FIG. 42.

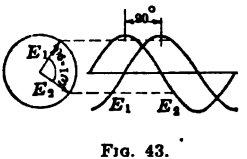

FIG. 43.

FIG. 41.—Symmetrical polyphase e.m.f's. (three-phase system).
FIG. 42.—Symmetrical polyphase e.m.f's. (quarter-phase system).
FIG. 43.—Unsymmetrical polyphase e.m.f's. (two-phase system).

**214. Symmetry of polyphase systems.** A polyphase system is called symmetrical if the applied voltages are equal and displaced in phase by equal amounts. The three-phase system (Fig. 41) and the quarter-phase system (Fig. 42) are symmetrical systems; the two-phase system (Fig. 43) is an unsymmetrical system.

**215. A balanced polyphase system** is one in which the sum total of the instantaneous power in all the phases is constant (non-pulsating). Thus, in a symmetrical three-phase system in which an equal load is applied to all the three phases, the power is constant, notwithstanding the fact that the power in each phase is pulsating.

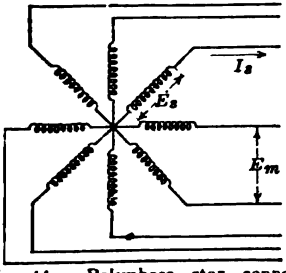

FIG. 44a.—Polyphase star connection.

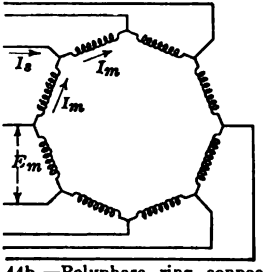

FIG. 44b.—Polyphase ring connection.

**216. Balance factor.** If the total power in a polyphase system is pulsating, the system is called unbalanced; the ratio of the instantaneous minimum value of power to the maximum value of power is called the balance factor of the system.

**217. Star and ring connections.** The two principal methods of connecting the separate phases of a polyphase system are the star connection (Fig. 44*a*), and the ring or mesh connection (Fig. 44*b*). In a symmetrical *n*-phase system, with the phases equally loaded, the relation between the star voltages $E_s$ and the mesh (or ring) voltages $E_m$ (Fig. 45*a*)

$$E_m = 2E_s \sin \frac{\pi}{n} \qquad (259)$$

Digitized by Google

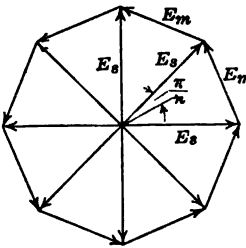

FIG. 45a.—Symmetrical star and ring e.m.fs.

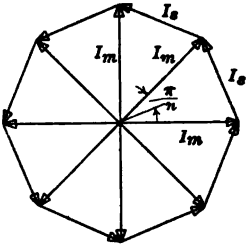

FIG. 45b.—Symmetrical star and ring currents.

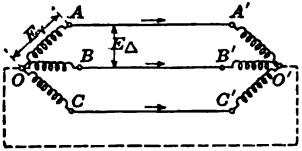

FIG. 46a.—Three-phase Y connection.

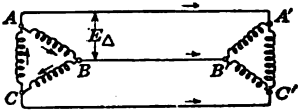

FIG. 46b.—Three-phase delta connection.

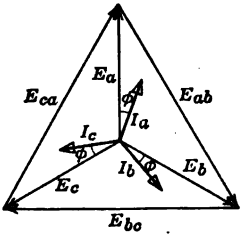

FIG. 47a.—Three-phase Y e.m.fs. and currents.

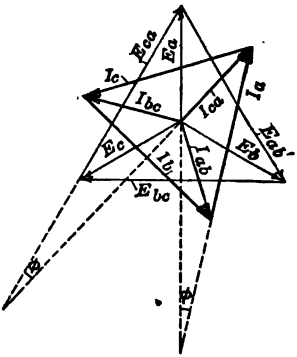

FIG. 47b.—Three-phase Δ e.m.fs. and currents.

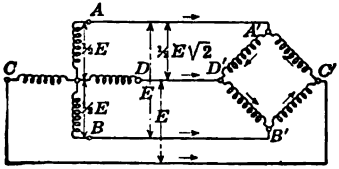

FIG. 48.—Two-phase system; star and ring connections.

Digitized by Google

The relation between the star currents $I_s$ and the mesh currents $I_m$ (Fig. 45*b*) is

$$I_s = 2I_m \sin \frac{\pi}{n}. \tag{260}$$

**218. Three-phase Y and Δ connections.** In a three-phase system the star connection is also called the Y-connection (Fig. 46*a*), and the mesh is called the delta connection (Fig. 46*b*). The relations of the currents and the voltages are (Figs. 47*a* and 47*b*).

$$E_\Delta = E_y\sqrt{3} = 1.732E_y, \text{ and } I_\Delta = \frac{I_y}{\sqrt{3}} = \frac{I_y}{1.732}. \tag{261}$$

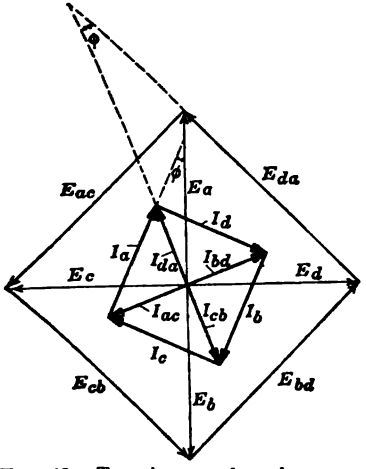

FIG. 49.—Two-phase e.m.fs. and currents.

**219. Two-phase star and ring connections.** In a two-phase system (Fig. 48) the relations of the currents and the voltages are (Fig. 49)

$$E_m = E_s\sqrt{2} = 1.414E_s; \quad I_m = \frac{I_s}{\sqrt{2}} = \frac{I_s}{1.414} = 0.7071I_s \tag{262}$$

where the subscripts $m$ and $s$ refer to the mesh and the star respectively. (Par. 217)

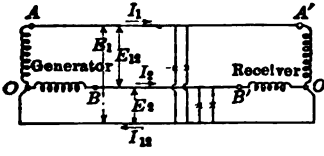

FIG. 50.—Two-phase three-wire system.

**220. Two-phase three-wire system.** With a two-phase three-wire system (Fig. 50) the current in the common or return wire is $\sqrt{2}$ times the current in each phase (Fig. 51), and the voltage between the phases is $\sqrt{2}$ times the voltage between each phase and the common return.

Digitized by Google

**221. Polyphase power.** The total power in a **symmetrical *n*-phase system** is given by the formula

$$P = nI_s E_s \cos\phi = nI_m E_m \cos\phi. \quad (263)$$

In an **unsymmetrical** or **unbalanced system** the **total power** is found by summing up the power in the separate phases.

**222. Three-phase power.** In a three-phase system (Fig. 46), the power

$$P = 3I_y E_y \cos\phi = 3I_\Delta E_\Delta \cos\phi = I_y E_\Delta \sqrt{3} \cos\phi \quad \text{(watts)} \quad (264)$$

if the currents are in amperes and the voltages in volts.

**223. Two-phase power.** In a **quarter-phase system** (Fig. 47) the power

$$P = 4I_s E_s \cos\phi = 4I_m E_m \cos\phi = 2\sqrt{2} I_s E_m \cos\phi \quad \text{(watts)} \quad (265)$$

**224. An equivalent single-phase circuit** is a circuit which is used in computations relating to polyphase transmission lines and machinery. For three-phase circuits some engineers use a single-phase circuit with a voltage equal to the Y-voltage of the three-phase system, and the power equal to that in one phase. Others use a single-phase circuit having a voltage equal to the delta voltage of the three-phase circuit, and transmitting the power equal to the total power in the three phases. Both methods lead to the same result, provided that the assumptions are consistently carried out.

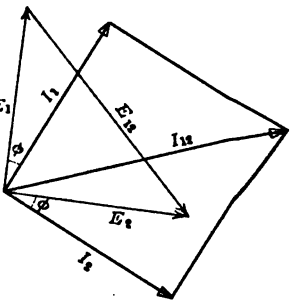

FIG. 51.—E.m.fs. and currents in two-phase three-wire system.

**225. Unbalanced polyphase circuits** are treated as separate single-phase circuits and then combined into one. Assuming a three-phase system with a line voltage triangle as shown in Fig. 52 and an unbalanced load, $E_1$, $E_2$ and $E_3$, are given. (They form the triangle *abc*.) Constructing semicircles on $E_1$, $E_2$, and $E_3$ as diameters, the e.m.f. triangle for each branch is constructed (Par. **155**). We have

$$\frac{E_1}{z_1} = i_1, \quad \frac{E_2}{z_2} = i_2 \text{ and } \frac{E_1}{z_3} = i_3. \quad (266)$$

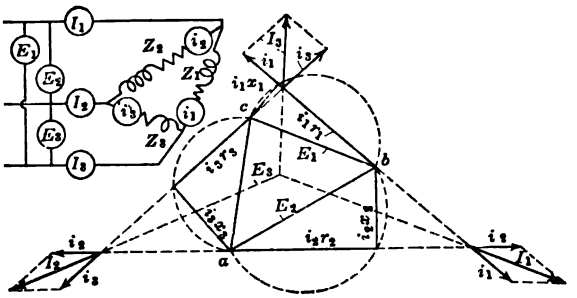

FIG. 52.—Unbalanced three-phase system.

The currents, $i_1$, $i_2$ and $i_3$, are in phase with the $ir$ drops in their respective branches. These can be conveniently combined by prolonging the $ir$ lines until they intersect, and laying off the currents, $i$, from the intersection. The main currents, $I_1$, $I_2$ and $I_3$, are found by taking the vector sum of the branch currents, $i_2$ and $i_3$, $i_3$ and $i_1$, $i_1$ and $i_2$, respectively.

**226. For further treatment of the current and voltage relations with unbalanced loads and unsymmetrical voltages** see the last few chapters, in Dr. Steinmetz's "Alternating-current phenomena"; also the author's "Experimental Electrical Engineering," Vol. II, Chapter 25, and his "Ueber mehrphasige Stromsysteme bei ungleichmässiger Belastung" (Enke, Stuttgart, 1900). For the "V" and "T" connections of transformers, and for six-phase connections, see Sec. 6, on transformers. Also see Sec. 11, on Power Transmission, for further treatment of the calculation of polyphase systems, and Sec. 12, on Distribution Systems.

## UNIFORMLY DISTRIBUTED RESISTANCE, REACTANCE, CAPACITY AND LEAKAGE

**227. Uniformly distributed properties.** In a **transmission line** the **resistance,** the **reactance,** and the **capacity** are **uniformly distributed.** Besides, there may be appreciable **leakage** to the ground or between the wires, which leakage for the purposes of computation may also be assumed to be uniformly distributed. Under such conditions the current along the line at any certain instant is different in different places; in other words, the current is a function not only of time $t$ but also of the distance $s$ from the receiver end.

**228. Continuous impressed e.m.f.** For a **direct-current line** possessing a resistance of $r$ ohms per unit length and a leakage conductance of $g$ mhos per unit length, the current and the voltage relations at a distance $s$ from the receiver end are expressed by the differential equations,

$$\frac{d^2i}{ds^2} = rge, \text{ and } \frac{d^2e}{ds^2} = rgi. \tag{267}$$

The solution of these equations is of the form

$$i = A_1\epsilon^{-ms} + A_2\epsilon^{ms}, \tag{268}$$

$$e = B_1\epsilon^{-ms} + B_2\epsilon^{ms}; \tag{269}$$

where $m = \sqrt{rg}$, and $A_1$, $A_2$, $B_1$ and $B_2$, are the constants of integration which are determined by the electrical conditions at some one point of the line.

**229. Solution of continuous-current case.** The solution of the foregoing differential equations is preferably expressed through **hyperbolic functions,*** in the form

$$i = C_1 \text{ Cosh } ms + C_2 \text{ Sinh } ms; \tag{270}$$

$$e = D_1 \text{ Cosh } ms + D_2 \text{ Sinh } ms; \tag{271}$$

where $C_1$, $C_2$, $D_1$, and $D_2$ are the constants of integration which depend upon the given conditions at some one point on the line. For example, if the receiver current $I_2$ and the receiver voltage $E_2$ are given, the constants have the following values:

$$C_1 = I_2;\ C_2 = E_2\frac{g}{m};\ D_1 = E_2;\ D_2 = I_2\frac{m}{g}. \tag{272}$$

Thus, knowing $i$ and $e$ at the receiver end, their values may be calculated for the sending end or for any point on the line. For further details see the first few chapters of A. E. Kennelly's "The Application of Hyperbolic Functions to Electrical Engineering Problems."

Another form of solution, employing the exponential method instead of the hyperbolic, will be found in the *Transactions* of the A. I. E. E.† for 1911, where the problem discussed is one of telegraphic transmission over long aerial-wire circuits by means of the closed-circuit Morse system widely used in America.

---

* For a simple theory of hyperbolic functions see Seaver's "Mathematical Handbook," Sec. III; also somewhat more advanced, "Hyperbolic Functions," by McMahon. The best tables of hyperbolic functions of real hyperbolic angles are probably those by Becker and van Orstrand, published by the Smithsonian Institution. Tables of hyperbolic functions of complex angles over a limited range will be found in the above-mentioned book by McMahon, and also in the *General Electric Review*, Supplement, May, 1910, and in the *Harvard Engineering Journal*, Vol. X, No. 4 and Vol. II, No. 2. A separate reprint of the latter tables is available.

Digitized by Google

**230. Alternating impressed e.m.f.** Let a sine-wave alternating voltage be applied to an equivalent single-phase line (Par. **224**) with uniformly distributed characteristics. Let the resistance and the inductive reactance of the line be $r$ ohms and $x$ ohms per unit length, respectively, so that the series impedance is $Z = r + jx$ ohms per unit length. Let the condensive susceptance and the leakage conductance be $b$ and $g$ mhos, per unit length respectively, so that the shunted admittance is $Y = g - jb$ mhos per unit length. The current and the voltage relations at a distance $s$ from the receiver end of the line are expressed by the differential equations

$$\frac{d^2I}{ds^2} = M^2 I, \text{ and } \frac{d^2E}{ds^2} = M^2 E \tag{273}$$

where $M = \sqrt{YZ}$. In these expressions $I$, $E$ and $M$ are complex quantities, (Par. **184**), and the magnitude and the phase of the current and the voltage vary from point to point, remaining at the same time sine functions. In other words, the current and the voltage are sine functions of time $t$, and such functions of $s$ as to satisfy the above-given equations. The parameter $M$ characterizes the line and is independent of either $t$ or $s$. The solution of these equations is of the form

$$I = A_1 \epsilon^{-Ms} + A_2 \epsilon^{Ms} \tag{274}$$

$$E = B_1 \epsilon^{-Ms} + B_2 \epsilon^{Ms}, \tag{275}$$

where the constants of integration $A_1$, $A_2$, $B_1$ and $B_2$ are complex quantities

These constants are determined by the electrical conditions at some one point of the line, for instance, when the current and the voltage at one point are given in magnitude and in relative phase position.

**231. Solution of alternating-current case.** The solution of the foregoing differential equations is preferably expressed through **hyperbolic functions** (Par. **229**) of the complex angle $Ms$. Namely,

$$I = C_1 \text{ Cosh } Ms + C_2 \text{ Sinh } Ms; \tag{276}$$

$$E = D_1 \text{ Cosh } Ms + D_2 \text{ Sinh } Ms; \tag{277}$$

where the complex quantities $C_1$, $C_2$, $D_1$, and $D_2$ are the constants of integration which depend upon the given conditions at some one point of the line.

For example, if the receiver voltage $E_2$ and the receiver current $I_2$ are given in magnitude and in phase (at $s = 0$) the constants of integration have the following values:

$$C_1 = I_2;\ C_2 = E_2 \frac{Y}{M};\ D_1 = E_2;\ D_2 = I_2 \frac{M}{Y}. \tag{278}$$

Thus, knowing $I$ and $E$ at the receiver end, their values may be calculated for the sending end or at any other point on the line.

**232. References to other literature.** For further details and application of the foregoing equations to power-transmission lines and to the propagation of currents in telephone and telegraph lines see C. P. Steinmetz, "Theory and Calculation of Transient Electric Phenomena and Oscillations;" J. A. Fleming, "The Propagation of Electric Currents in Telephone and Telegraph Conductors."

## MEASUREMENTS AND MEASURING APPARATUS

### ELECTRIC AND MAGNETIC MEASUREMENTS

BY F. MALCOLM FARMER, M.E.

#### GENERAL

**1. The measurement of any given quantity** is the comparison of that quantity with another quantity of the same kind which has been chosen as a unit. The **unit** may be a purely arbitrary quantity with no rational significance, such as the foot and the pound, or it may have a very definite meaning, as the centimeter and the gram. The units used in electrical measurements belong to the latter class because they are based on the **centimeter-gram-second** or **C.G.S.** system. The C.G.S. system (Sec. 1) is the fundamental system upon which all physical measurements have been based, on the theory that all physical phenomena are the result of matter and motion, that is, space (centimeters), mass (grams) and time (seconds).

**2. Measurements classified according to precision.**—Electrical measurements may be divided, in a very general way, into three classes. (a) **High-precision measurements**, such as those made at the various national standardizing laboratories in connection with the establishment and maintenance of standards. Every precaution is observed to obtain the highest possible degree of accuracy. Expense is a secondary consideration. (b) **Commercial laboratory measurements**, where the object is to secure results which are reliable and accurate, but only to the degree justified by commercial and engineering requirements. The cost must be a minimum. (c) **Commercial measurements** are those involved in the production, distribution and sale of energy. The scope of the subject in this section is limited to the last two classes.

**3. A standard** is a concrete representation of a unit. The fundamental C.G.S. units are difficult to represent and early in the development of the art the need for a system of units which could be used in electrical measurements was recognised, and resulted in the establishment of the "practical" units (see Sec. 1). These units are derived from the fundamental C.G.S. units and can be represented by definite, concrete and reproducible standards.

The distinction drawn between primary and secondary standards is largely a matter of viewpoint. In general, however, primary standards may be considered as those which represent directly by definition the unit involved, such as the mercury ohm, the silver voltameter and the saturated cadmium cell, made according to certain specifications. Secondary standards are the more practicable working standards which are standardised by comparison with primary standards and used as the basis of all ordinary measurements. They include, for example, the manganin standard resistances and the ordinary Weston-type standard cell. Primary standards are, in general, maintained only by the government custodians of the standards in the various countries; whereas secondary or working standards, based on these primary standards, serve as the fundamental basis of practical measurements in engineering and commercial fields.

**4. The precision obtainable** in an electrical measurement depends upon the various factors which enter into the determination; among these are the correctness of the principle employed and the method used, accuracy of the standards, number and magnitude of possible errors, correctness of calculations and so forth. In precision measurements, as classified above, a precision of one part in 100,000 in certain classes of measurements is regularly attained. In commercial measurements, the cost of such a high degree

Digitized by Google

of precision is not justified. The limits, however, are being gradually raised as the art develops and greater refinements are introduced. The table given in Par. 5 indicates the precision which may be reasonably expected in various classes of measurements made by average observers, under ordinary conditions, and with standard commercial instruments.

**5. Table of Average Precision to be Expected in Various Classes of Commercial Measurements**

| Class of Measurements and Method | Probable precision, per cent. |
|---|---|
| (Deflections of two-third scale assumed in indicating instruments) | |
| ***Current*** | |
| Potentiometer, high-grade types | 0.03 |
| Portable ammeter, continuous-current | 0.4 |
| Portable ammeter, alternating-current | 0.5 –1.0* |
| Switchboard ammeter, continuous-current | 1.5 |
| Switchboard ammeter, alternating-current | 1.0 –2.5* |
| Recording instruments | 1.5 –3.0 |
| ***Potential*** | |
| Potentiometer, high-grade type | 0.02 |
| Portable voltmeter, continuous-current | 0.25 |
| Portable voltmeter, alternating-current | 0.5 –1.5* |
| Switchboard voltmeter, continuous-current | 1.0 |
| Switchboard voltmeter, alternating-current | 1.0 –2.5* |
| Recording instruments | 1.5 –3.0 |
| High potentials (in testing of insulators, etc.) | 5.0 |
| ***Power*** | |
| Portable wattmeters | 1.0 |
| Laboratory wattmeters (non-portable or semi-portable) | 0.25 |
| Switchboard wattmeters | 2.0 |
| Recording instruments | 2.0 –4 0 |
| ***Energy*** (watt-hour meters) | |
| Continuous-current | 2.5 |
| Alternating-current, single-phase, no transformers | 2.0 |
| Alternating-current, single-phase with transformers | 2.5 |
| Alternating-current, polyphase with transformers | 3.0 |
| ***Frequency*** | |
| Portable instruments | 0.5 |
| Switchboard instruments | 1.5 |
| ***Power-factor*** | |
| Portable instruments (ammeter, voltmeter, wattmeter) | 2.0 |
| Switchboard instruments (above 90 per cent.) | 1.0 |
| Switchboard instruments (below 90 per cent.) | 2.0 –4.0 |
| ***Resistance*** | |
| Medium: Wheatstone bridge, high-grade, 1.0 to 10,000 ohms. | 0.1 |
| Wheatstone bridge, high-grade, less than 1 ohm, over 10,000 ohms | 0.2 –1.0 |
| Portable bridges | 0.5 –2.0 |
| Low: Fall-of-potential method | 0.5 |
| Thomson double bridge | 0.05 |
| High: (Insulation) | 5.0 |
| ***Conductivity*** | 0.25 |
| ***Magnetic measurements*** | 2.5 |

**6. Classes of errors.** There are two general classes of errors in any kind of measurements, *a*, systematic and *b*, accidental. The former class affects each result in a series of similar observations in the same manner, as for example, an error in the standard used. The latter class includes those over which the observer has no control, such as observational errors in reading an indicating instrument. Accidental errors, unlike systematic errors, are as likely to be positive as negative and therefore tend to eliminate themselves

* Depends upon capacity and whether used with instrument transformers.

Digitized by Google

from the mean value as the number of readings is increased. Where the necessary degree of reliability is not obtained in a single measurement, a number of observations are made, from which the most probable true value may be obtained, together with its probable error. These latter quantities may be derived in different degrees of precision by various mathematical methods involving the theory of probabilities and the method of least squares. In all ordinary electrical measurements it will usually be sufficiently correct to assume that the true value is equal to the average of the various values obtained (eliminating systematic errors) plus or minus the average error. The average error is the average of the differences between the average value and each individual value. It should be noted, however, that according to the theory of probability, the precision of the result does not increase directly but only as the square root of the number of observations made (see Par. 426 to 435).

7. **Certain general precautions** which should be observed in electrical measurements, and certain sources of error which should be avoided, are indicated in the following paragraphs.

(a) **The probable limit of accuracy** of the standards, instruments and methods should be known.

(b) As a general proposition, in other than rough determinations, one measurement should not be relied upon. Several readings should be taken, and the conditions should be altered, wherever possible, in order to avoid accidental errors.

(c) Indicating instruments should be of such a range that the quantity under measurement will produce a reasonably large deflection on the scale. The percentage observational error decreases in direct proportion as the magnitude of the deflection increases.

(d) The possible presence of **external or stray magnetic fields**, both direct and alternating, should always be borne in mind. Such fields may be produced by current in neighboring conductors, or by various classes of electrical machinery and apparatus, structural iron and steel in buildings, etc. These fields introduce errors by combining with the fields of portable indicating instruments, galvanometers and other instruments utilising a magnetic field, and, in the case of alternating fields, by inducing small e.m.fs. in the loops formed in bridges, potentiometers, etc.

(e) In measurements involving high resistances and galvanometers, such as bridges and potentiometers, possible "leakage" or shunt circuits should be eliminated. This is done by providing a "**guard**" **circuit** the principle of which is to keep all points to which the current might flow improperly, at the same potential as the highest in the apparatus. See further discussion under potentiometers (Par. 49 to 52).

(f) **Temperature changes** in various parts of bridge, potentiometer and similar circuits should be avoided because of thermo e.m.fs. produced at the junction of dissimilar metals. Such effects are often produced if the observer's hand comes in contact with the metal parts of the galvanometer key, switches, etc.

(g) Instruments with covers made of glass and hard rubber should not be rubbed, especially with a dry dust cloth. The induced electrostatic charge on the moving element is often sufficient to change the deflection materially.

(h) At potentials of 500 volts and above, the electrostatic attraction between moving and fixed parts may become serious. This is prevented by keeping the two parts at the same electrostatic potential. When grounding is permissible, this can be done by connecting the circuit to earth at the point where the instrument is connected, care being taken that the moving-coil end of the instrument is on the ground side. In very high potential work this electrostatic attraction becomes very troublesome, so that the instruments must be connected in circuit at a grounded part of the line, or else be thoroughly insulated from ground and the moving element connected to the case or to an electrostatic shield around the instrument.

## GALVANOMETERS

8. **Galvanometers** are used extensively in all classes of electrical measurements. Strictly speaking, the term applies to many other instruments for measuring current, such as voltmeters and ammeters, but it is ordinarily understood to apply to those instruments which are used to measure very small electrical quantities.

Digitized by Google

**9. Classes of galvanometers.** There are two general classes: (1) **moving magnetic needle**; (2) **moving coil.** In the former class, a small and (usually) permanent magnet is suspended at the centre of a coil of wire through which flows the current to be measured, producing a deflection. In moving coil galvanometers, a coil of relatively fine wire is suspended at the centre of a permanent or electromagnetic field; the current to be measured flows through this coil, producing a deflection. Moving-magnet instruments are most prominently represented by the tangent galvanometer and the Kelvin galvanometer; moving-coil instruments by D'Arsonval and electrodynamometer type galvanometers.

**10. Direct-current types of galvanometers** are represented by the following: Tangent galvanometers, sine galvanometers, the Kelvin type, D'Arsonval type, ballistic type, differential galvanometers, electrodynamometers and electrometers. These are described briefly in the following paragraphs.

**11. Tangent galvanometers.** In this instrument the magnetic needle is suspended or pivoted above the centre of a circular scale, over which moves the pointer attached to the magnet. The coil carrying the current is in a plane perpendicular to that of the scale, so that the direction of the field which it produces is in the plane of the magnet, the earth's magnetic field being the directing force. The current is approximately

$$I = \frac{5rH \tan \alpha}{\pi n} \quad \text{(amp.)} \qquad (1)$$

where $r$ = radius of coil in centimeters; $H$ = horizontal component of earth's field in gauses; $n$ = number of turns in coil; and $\alpha$ = angle of deflection.

**12. The sine galvanometer** is similar to the tangent galvanometer, the essential difference being that the coil is moved as the needle deflects, so that they are finally in the same plane. In this instrument, the above formula becomes:

$$I = \frac{5rH \sin \alpha}{\pi n} \quad \text{(amp.)} \qquad (2)$$

**13. Kelvin galvanometer (astatic type).** In this instrument there are two magnetic needles or sets of needles, of slightly different strengths, at opposite ends of a light quartz rod and oppositely directed. Each is at the centre of a pair of coils through which flows the current to be measured, these pairs being oppositely wound so that the moment exerted on the two needles is in the same direction. Thus the moving system is almost, but not quite, astatic. The controlling force is the earth's field modified as desired by means of a movable permanent magnet. This galvanometer must be calibrated against a standard. It is one of the most sensitive types of galvanometers known, instruments with a current sensibility of the order of $1 \times 10^{-12}$ amperes having been built and used in research work.

**14. Moving coil or D'Arsonval galvanometers** consist of a coil of fine wire suspended between the poles of a permanent horse-shoe magnet. The coil is usually suspended by a phosphor-bronze or steel wire, or flat strip, which not only conducts the current to the coil but provides the controlling force. Current is conducted from the coil by a helix of fine wire at the bottom. The strength of the field in the region occupied by the coil is increased by mounting a soft iron core in the central space enclosed by the coil, the pole pieces being shaped to give a uniform field throughout the space in which the coil moves. While the D'Arsonval galvanometer cannot readily be used to make absolute measurements, but requires calibration, its many advantages have made this the most generally used type of galvanometer in the electrical laboratory. It is practically independent of the earth's field or other external fields; its period can be made short, which, with its dead-beat qualities, makes it a much faster instrument than other types; it is comparatively rugged, simple to use and one instrument can be employed for a wide range of work.

**15. Ballistic galvanometers** are used to measure quantity of electricity (coulombs); such, for example, as the discharge from a condenser or the induced charge in a secondary circuit. Ballistic galvanometers may be of the moving-magnet or the D'Arsonval type. In order that the instrument may be perfectly ballistic the quantity to be measured must be completely dis-

Digitized by Google

charged through it before the suspended system has moved appreciably. **The period**, or time of vibration, must therefore be long compared with the time of discharge. This is accomplished by increasing the inertia of the moving system.

**16. Deflection of ballistic galvanometers. The magnitude of the first deflection** is a measure of the quantity discharged into the instrument. In an instrument in which there is no damping (Par. 26) such as the moving magnet type, the quantity may be calculated directly from the constants of the instrument. Thus

$$Q = \frac{2Ht \sin (\frac{1}{2})\alpha}{\pi G} \quad \text{(coulomb)} \quad (3$$

or for small angles, 5 deg. or less,

$$Q = \frac{Ht \sin \alpha}{\pi G} \quad \text{(coulomb)} \quad (4$$

where $Q$ = quantity of electricity in coulombs, $H$ = field strength in gausses, $G$ = constant computed from the coils, $t$ = period in seconds, $\alpha$ = angle of deflection.

**17. Ballistic galvanometer constant.** In practice, ballistic galvanometers are usually standardised and the formula becomes very simple, $Q = kd$ where $d$ = deflection and $k$ = quantity per unit deflection or galvanometer constant. The constant is determined with a standard condenser or mutual inductance. The deflection obtained upon suddenly discharging a charged condenser through the galvanometer is $d = Q = CE$; and hence $k = CE/d$, where $Q$ = quantity of electricity in coulombs, $E$ = potential to which the condenser had been charged in volts, and $C$ = capacity of condenser in farads. When a mutual inductance is used, the deflection is $d = Q = MI/R$ and $k = MI/dR$, where $Q$ = quantity of electricity in coulombs, $M$ = coefficient of mutual inductance in henrys, $I$ = steady or Ohm's law value of current in primary of mutual inductance in amperes, and $R$ = resistance of secondary circuit (including the mutual inductance) in ohms.

**18. A differential galvanometer** is one provided with two independent coils or sets of coils by means of which two currents may be compared simultaneously. This method provides a means of measuring a current without making the circuit common with that of the comparison standard. In D'Arsonval instruments, the two coils are wound side by side on the same frame and are connected in opposition, so that when the two currents being compared are adjusted for zero deflection, their ratio is usually unity. The actual ratio can be determined experimentally.

**19. Electrometers.** In the electrometer, a piece of thin aluminium leaf suspended by a metallic suspension over four quadrants of sheet metal which are insulated from each other and from the frame or support. Opposite quadrants are connected to each other and the two sets are connected respectively to the two sides of the circuit to be measured. If a charge from a condenser is placed on the moving vane, one end will be repelled and the opposite end attracted, producing a deflection which will be a measure of the potential applied to the stationary quadrants. This instrument is extremely sensitive, and while it is one of the earliest types of electrical measuring instruments it is still used extensively in research work, especially where the available energy is extremely small, as in measurements of radiant energy.

**20. Galvanometers as detectors.** The majority of galvanometers are used as detectors only, that is, in zero-deflection methods where the kind of scale or proportionality of deflections does not enter into the determination. In such cases a very short, straight scale is sufficient and space may be economized by placing the galvanometer on the wall above the table, with the scale directly underneath. The beam of light is properly directed by suitable prisms and mirrors.

**21. Reflecting galvanometers** may be read with a telescope and scale, or with a lamp and scale. In the former, the scale is reflected from the plane mirror (attached to the moving system) to the telescope through which movements are observed. In the latter, an image of a narrow beam of light (issuing from a narrow slit in a vessel enclosing a lamp, or from a portion of an incandescent lamp filament) is thrown on to the scale by the mirror. In

Digitized by Google

order to get a sharp image, either the mirror is made concave (with a 1-m. focus if the scale is the usual distance of 1 m. away), or a lens is used. Fig. 1 shows the general arrangement.

**22. Galvanometer scales.** When readings are to be taken, care should be exercised that they are proportional to the angular deflections. On a straight scale the deflection in millimeters is

$$d = A \tan 2\alpha \qquad (5)$$

where $A$ = distance from mirror to scale in millimetres and $\alpha$ = angle through which the moving coil turns. If the angle is small, $d$ is proportional to $\alpha$. The error becomes about 0.5 per cent. at $\alpha = 5$ deg. Obviously a curved scale will eliminate this error, and by properly adjusting the curvature the readings may be made proportional to the angle or to any desired function of the angle.

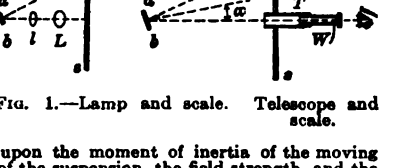

FIG. 1.—Lamp and scale. Telescope and scale.

**23. The sensibility of a galvanometer** is expressed in one of several ways, the numerical expression of which is called the **galvanometer constant.** In instruments of the D'Arsonval type, the sensibility depends upon the moment of inertia of the moving system, the torsional moment of the suspension, the field strength, and the number of turns and the area of the coil.

**24. Different forms of galvanometer constants.** The various constants are usually defined as follows:

(a) **The ampere constant** is the current in microamperes (millionths of an ampere) which will produce 1 mm. deflection on a scale 1 m. distant.

(b) **The megohm constant** is the number of megohms in series with the galvanometer through which one volt will produce 1 mm. deflection on a scale 1 m. distant.

(c) **The volt constant** is the potential in microvolts (millionths of a volt), across the galvanometer terminals which will produce a deflection of 1 mm. on a scale 1 m. distant. Or it may be expressed as the deflection in millimeters which will be produced by one microvolt.

(d) **The coulomb constant** refers to ballistic galvanometers (Par. 17) and is the quantity in microcoulombs (millionths of a coulomb) which will produce 1 mm. deflection on a scale 1 m. distant.

**25. High current sensibility** is desirable for high-resistance measurements, such as insulation resistance. **High voltage sensibility** is desirable for measurements involving small potentials, such as low-resistance bridges, potentiometers, etc. **High coulomb sensibility** is desirable in magnetic tests.

**26. Damping.** This term is applied to those forces which collectively bring the moving system to rest after it has been set in motion. In order to shorten the period and facilitate readings, damping sometimes is intentionally produced mechanically with air vanes, or more generally by electrical means. The latter means include: (a) use of a metal frame on which the moving coil is wound and in which eddy currents are produced; (b) use of a closed loop of copper wire attached to the coil and in which eddy currents are produced; (c) use of the generator action of the swinging coil when its circuit is closed. The latter is the more convenient method for general purposes, because the damping can be readily changed by means of resistances in series or in parallel with the galvanometer.

**27. Critical damping** is that condition of damping where the moving system comes to zero position, or equilibrium, but does not pass through it, in the shortest time after deflection. A galvanometer is **aperiodic** when it is critically damped. It is **dead beat** when the coil deflects to its final position or reading without oscillation.

**28. The period of a galvanometer** is the time in seconds required for one complete oscillation, or the time between two successive passages through the zero or mid-position.

Digitized by Google

**29. Galvanometer shunts** are combinations of resistances so arranged and so connected to the galvanometer that the constant of the latter may be quickly changed. Ordinary resistance boxes may be used as shunts for galvanometers when the resistance of the galvanometer circuit is not too small. In the latter case the box is connected as shown in Fig. 2, thus increasing the resistance $R_g$ of the galvanometer circuit. The readings of the galvanometer must be multiplied by a factor

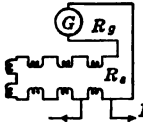

FIG. 2.—Galvanometer shunt.

$$k = \frac{R_g + R_s}{R_s} \tag{6}$$

wherein $R_g$ is the resistance of the galvanometer circuit and $R_s$ is that of the shunt. In special galvanometer shunts,

$$R_s = \frac{R_g}{9}, \frac{R_g}{99}, \frac{R_g}{999}, \frac{R_g}{9999}, \quad \ldots\ldots \text{ etc.} \tag{7}$$

then $k = 10$, 100, 1,000, 10,000 respectively.

**30. The Ayrton or universal shunt** is so arranged that it can be used with any galvanometer. When, in Fig. 3, the movable contact $x$ is at $b$, $I'_g = Ir_{ab}/(r_{ab}+r_g)$, where $I'_g$ = current through galvanometer, $I$ = current from battery, $r_{ab}$ = resistance between $a$ and $b$, and $r_g$ = resistance of galvanometer. If the contact $x$ is moved to $c$,

$$I''_g = I'_g\left(\frac{r_{ac}}{r_{ab}}\right) \qquad \text{(amp.)} \tag{8}$$

It will be noted that $r_g$ is not in this equation; hence if the galvanometer constant is obtained with the shunt all in ($x$ at $b$), the shunt ratio at any other position of $x$ is $r_{ac}/r_{ab}$ and is independent of the galvanometer resistance.

**31. Alternating-current types of galvanometers** include the following: Electrodynamometers, or, as they are more commonly known, dynamometers; vibration galvanometers, thermogalvanometers, electrostatic galvanometers, alternating-current detectors, barretters and bolometers.

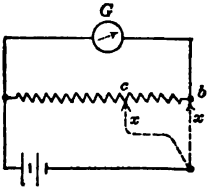

FIG. 3.—Universal galvanometer shunt.

**32. Dynamometer-type instruments** are used extensively in measurements of alternating currents because they measure mean effective values and can be calibrated on direct current. They can be used for a wide range of measurements of current, e.m.f. and power, from extremely small values to very large ones.

**33. The operative principle of the dynamometer** is the electrodynamic action between a movable coil (or coils) suspended between two or more fixed coils, all of which are energized. **The Rowland electrodynamometer*** is typical of this class of instruments. It consists simply of two fixed coils mounted close together, between which is suspended a small coil of very fine wire. Each fixed coil consists of two separate windings of different current capacities brought out to separate terminals. For e.m.f. measurements the moving coil and the fine wire fixed coils are connected in series; for current measurements, the moving coil is connected across a non-inductive shunt in the current circuit; for power measurements, the moving coil is connected across the circuit to be measured while the proper fixed coil is connected in series with it.

**34. Dynamometers are made astatic,** or independent of external fields, by having two sets of moving coils, oppositely wound, one above the other, with a common suspension. There may be one or more pairs of fixed coils. In heavy-current instruments, the fixed coils are wound with cable composed of many fine strands laid up in braided form. This reduces the eddy currents which otherwise would be set up and which would influence the moving coil.

Digitized by Google

**35. Vibration galvanometers*** can be used only with alternating currents. There are two types, the **coil** and the **soft-iron magnet.** In the former, the moving element is a single wire or narrow coil of very fine wire suspended between the poles of a permanent magnet. An exceedingly small mirror is attached at the centre of the wire or coil. When the natural period of this moving system coincides with that of the current to be measured it will resonate and be sensitive to extremely small currents, the indication being the width of the spot of light on the screen or scale. The instrument is "tuned" or adjusted to resonance by changing the effective length of the suspension or its tension.

In the soft-iron magnet type, a very small piece of soft iron is suspended by a silk fibre between the poles of a permanent horse-shoe magnet. Adjacent is a coil carrying the alternating current to be measured, which produces a field perpendicular to that of the permanent magnet. The temporarily magnetized needle vibrates in synchronism with the period of the alternating current and with an amplitude proportional to the strength of the current. The effective period of the moving system is adjusted to resonance, by shunting more or less of the permanent field by means of a movable keeper across the limbs of the magnet. Obviously these instruments can be used only for detector purposes, that is, in zero-method measurements, such as inductance and capacity measurements with a Wheatstone bridge.† They are extremely sensitive, being capable of detecting currents of the order of $1 \times 10^{-8}$ amp. and are applicable to frequencies up to 1,000 cycles per sec.

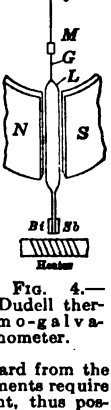

FIG. 4.—Duddell thermo-galvanometer.

**36. Thermo-galvanometers** utilize the heating effect of an electric current and are independent of frequency. They can be constructed with practically no inductance or electrostatic capacity, and are therefore used extensively in high-frequency measurements. One of several forms is the Duddell type, Fig. 4, in which a moving coil, suspended between the poles of a permanent magnet as in D'Arsonval galvanometers, includes a bismuth-antimony thermocouple placed immediately near an electric heater through which passes the current to be measured. The instrument can be used for a wide range of measurements by changing the heater. It can be used on frequencies up to the order of 100,000 cycles per sec.

**37. Electrostatic galvanometers** utilise the force of repulsion between two bodies carrying electrostatic charges of the same polarity. One or more very thin metal vanes are suspended by a fine wire between two or more stationary vanes, so shaped (circular discs with opposite quadrants cut away) that when excited, the movable vanes swing outward from the fixed vanes between which they are interleaved. These instruments require no appreciable current and can be calibrated on direct current, thus possessing characteristics which make them valuable for measuring e.m.fs. where the current capacity is very small or nil.

**38. Alternating-current detectors.** Other methods of determining the condition of balance in zero-method alternating-current measurements are shown in Figs. 5 and 6. The former indicates the scheme of a **synchronous commutator.**‡ A commutator, $C$, and two slip-rings, $r$ and $r^1$, are mounted on the shaft of a small synchronous motor. The bars in the commutator are narrow, and equal in number to the poles of the motor and equally spaced. Two brushes, $a$, $a^1$, connected to the galvanometer are so spaced as to bridge two bars simultaneously. These brushes are mounted on a disc which can be rotated about the shaft. The bars are connected alternately to the two

Digitized by Google

rings which in turn are connected through the brushes, $b$, $b^1$, to the alternating current being measured. It is apparent that the connections to the galvanometer are reversed every half cycle, so that the indication is a steady one, the value of which may be made anything from zero to a maximum by shifting the angular position of the brushes. Thus the most sensitive position can be readily found, irrespective of the phase relation between the current in the circuit being measured and the motor armature. The variation in contact resistance at high speeds, and possible presence of thermo e.m.fs., may cause trouble where the resistances or potentials are very low, as in low-resistance bridge measurements.*

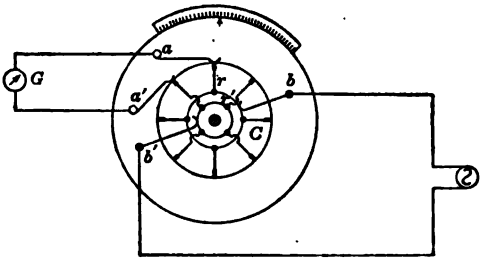

FIG. 5.—Synchronous commutator.

**39. A synchronous reversing key** which overcomes the latter difficulty is indicated in Fig. 6. A cam, $C$, mounted on the shaft of a small synchronous motor is so designed that it moves the lever, $l$, up and down in such a manner that the pair of contacts, $a$ and $a^1$, at the end of the lever make alternate contact with the pairs of stationary contacts, $c$ and $c^1$, once per cycle. The number of projections on the cam of course will correspond with the number of pairs of poles on the motor. The contacts are arranged as shown diagrammatically at the right of Fig. 6, from which it will be seen that the connections to the galvanometer are reversed every half cycle, so that a steady deflection is obtained in the direct-current galvanometer. All the contacts are sup-

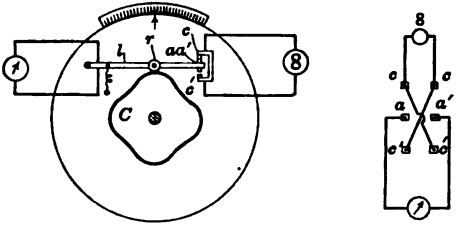

FIG. 6.—Synchronous reversing key.

ported on a solid disc which can be rotated around the shaft, and hence reversal can be made at any point on the wave as in the case of the synchronous commutator. The contacts are all made of platinum, the cam is hardened steel and the lever $l$ is kept in contact with the cam at all times by means of a spring. The roller $r$ is necessary to insure contact at the low portion of the cam.

**40. A barreter** * **is a bridge arrangement (Par. 143) in which the change in resistance with the passage of current of a high temperature coefficient wire is utilised to measure currents of telephone magnitude and frequency.**

**41. A bolometer is an instrument devised by Prof. S. P. Langley with which extremely small temperature changes (order of 0.0001 deg. fahr.) may be measured. A very thin strip of platinum or other metal is exposed to the radiation from the source being measured. This strip forms the arm of a balanced Wheatstone bridge and the change in resistance corresponding to the change in temperature is indicated by the galvanometer deflection.**

## CONTINUOUS-E.M.F. MEASUREMENTS

**42. Standards of e.m.f. The legal unit of e.m.f. in the United States is the international volt adopted by Act of Congress in 1894; in practice the prefix is generally omitted. This unit is the e.m.f. which, when applied to a conductor having a resistance of one international ohm, will produce a current of one international ampere. The Act also states that the volt "is represented sufficiently well for practical use by 1000/1434ths of the e.m.f. between the poles or electrodes of the voltaic cell known as Clark's cell at a temperature of 15 deg. cent. and prepared in the manner described in the accompanying specification." The Clark cell has since been superseded by the Weston cell as the standard of e.m.f. The value of the latter as adopted by the Bureau of Standards, Jan. 1, 1911 is 1.0183 at 20 deg. cent., which is now the standard of e.m.f. in this country.**

**43. The Clark cell was the first form of voltaic cell to meet the requirements of a reliable standard of e.m.f., namely, reproducibility and reasonable permanence. The elements are: positive electrode, metallic mercury; negative electrode, amalgamated zinc; electrolyte, saturated solution of zinc sulphate and mercurous sulphate. Its e.m.f. in terms of fundamental or e.g.s. units was originally taken as 1.434 international volts at 15 deg. cent., the value having been made legal in 1894 as stated above. Later and more careful determinations have shown, however, that 1.4328 is a more correct figure. The e.m.f. of the Clark cell changes with temperature in accordance with the formula:**

$$E = 1.4328[1 - 0.00077(t° \text{ C.} - 15)] \qquad (9)$$

**where $E$ = international volts at any temperature, $t$ deg. cent.**

**44. Objections to Clark cell. As the electrical art developed and more precise working standards became necessary, the defects in the Clark cell were noted. The most conspicuous of these are large temperature coefficient, large temperature lag and difficulty in obtaining the temperature. This cell has therefore been superseded by the Weston cells, which are practically free from these objections.**

**45. Weston cells.† There are two forms of Weston cells, the saturated cell and the unsaturated cell. The elements are: positive electrode, metallic mercury; negative electrode, amalgamated cadmium; electrolyte, solution of cadmium sulphate and mercurous sulphate.**

**46. Weston normal cell. In this cell the electrolyte is saturated. This form is the official standard because it is more permanent and can be reproduced with greater accuracy than when the electrolyte is unsaturated. When carefully made according to the official specifications, cells will agree with each other within a few parts in 100,000. The e.m.f. changes slightly with temperature according to the following formula:**

$$E = 1.0183[1 - 0.000041(t° \text{ C.} - 20)] \qquad (10)$$

**where $E$ = international volts at any temperature, $t$ deg. cent.**

**47. The unsaturated Weston cell, on the other hand, has practically no temperature coefficient (0.00001 per deg. cent.). Although it is not so reliable as a fundamental standard as the Weston normal cell, and each cell has to be standardised, it is, nevertheless, more convenient for general use. This is the form furnished by the Weston Electrical Instrument Co. The makers recommend that these cells be not subjected to temperatures below**

Digitized by Google

4 deg. cent. or above 40 deg. cent., and that no current greater than 0.0001 amp. be passed through them.

**48. Comparisons of continuous electromotive forces with a standard cell.** Electromotive forces may be compared with a standard cell by several methods. The more typical methods are based on the following principles.

(a) In the **substitution method**, the current flowing through a high resistance (not less than 15,000 ohms) is measured with a high-sensibility galvanometer, first with the standard cell in the circuit and then with the unknown e.m.f. substituted for the standard cell. The resistance being the same in the two cases, the deflections are proportional to the e.m.fs. $E = cd'/d$, where $E$ = unknown e.m.f., $e$ = standard cell e.m.f., $d$ = deflection with standard cell and $d'$ = deflection with unknown e.m.f.

(b) The **equal deflection method** is a modification of the above, in which the deflections are kept the same in the two cases by changing the resistance. Then $E = er'/r$, where $r$ = total resistance of the circuit, including the galvanometer, with the standard cell in the circuit and $r'$ = total resistance with the unknown e.m.f. This method is better than (a) because it is a constant deflection method and the result depends on the known values of two resistances, rather than observed deflections.

(c) In **Wheatstone's modification** of the equal deflection method, the galvanometer resistance does not have to be known. The deflection, $d$, is noted when the unknown e.m.f., $E$, and a known high resistance are in circuit. Additional resistance, $r'$, is added and the deflection, $d'$, again noted. Similarly with the standard cell of potential difference, $e$; the resistance is adjusted until the same deflection, $d$, is obtained and then an amount of resistance, $r$, is added until the deflection $d'$ is again obtained. The unknown e.m.f. is $E = er'/r$.

(d) In the **condenser discharge method** a condenser is charged, first from the unknown e.m.f., then from the standard cell, and discharged in each instance through a ballistic galvanometer. The deflections will be proportional to the e.m.fs., hence $E = ed'/d$ as in (a). Obviously, if the unknown e.m.f. is much smaller or much larger than the standard cell, the deflection can be made about equal to that of the standard cell by using a larger or a smaller condenser. In that case the ratio of the capacities should be known, and then $E = cd'C'/dC$, where $C$ = capacity of condenser used with the unknown e.m.f. and $C'$ = capacity of condenser used with the standard cell. This method has the advantage that practically no current is required, which is advantageous in making measurements of voltaic cells of very small capacity or rapid polarization.

(e) The principle of the **opposition or potentiometer method** is that of opposing the e.m.f. of the standard cell against an equal difference of potential which bears a known proportion to the unknown e.m.f. This method is the most accurate and by far the most generally used, because it is both a zero-deflection and a zero-current method, the result depending only on the ratio of two resistances which can be very accurately determined. Potentiometers are instruments employing this principle (Par. 49).

**49. Description of Leeds and Northrup potentiometer, low resistance type.** Fig. 7 shows the arrangements of the circuits. The figures for the second decimal place and beyond are obtained from a slide wire at the end of the circuit, $CB$, along which a contact moves. A special dial is also provided for the standard cell (at the left) and separate contacts are provided for the standard-cell e.m.f. and the unknown e.m.f., so that no settings have to be disturbed when checking the secondary current in the potentiometer circuit. The essential part of the instrument consists of 15 five-ohm coils, $AC$, connected in series with the extended wire, $CB$, the resistance of which from 0 to 1,100 scale divisions is 5.5 ohms. Thus when the current from the battery, $B$, is adjusted by the rheostat, $R$, to 0.02 amp., the fall of potential across each 5-ohm coil in $AC$ is 0.1 volt and across $CB$, 0.11 volt. Since the latter is divided into 1,100 parts, the e.m.f. may be measured to 0.0001 volt. At point 5 in $AC$, a wire is permanently attached connecting to one point of the double switch, $U$. When this switch is thrown to the left, the standard cell is connected through the galvanometer to point 5 and the sliding contact $T$ which moves over the dial at the left consisting of 19 resistance coils. Between $a$ and $A$ is a resistance which is adjusted to such a value that with 0.02 amp. flowing, the potential drop between 5 and $a$ is

Digitized by Google

1.0175 with 0.0001 volt additional drop across each dial coil, giving a maximum of 1.0194. This range will include the usual differences between different Weston standard cells. To adjust the current to 0.02 amp., throw the switch $U$ to the position indicated by the dotted lines, set the contact $T$ to correspond to the e.m.f. of the standard cell and regulate $R$ until the galvanometer shows no deflection. The unknown e.m.f. is then measured by throwing the switch $U$ to the position indicated by the full lines and adjusting the contacts $M$ and $M'$ until no deflection is noted. After a balance has been obtained, the current may be checked by simply shifting $U$ to the first position and pressing the contact key.

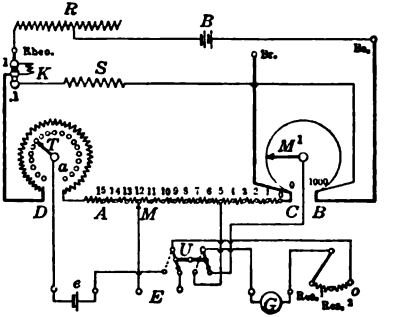

FIG. 7.—Leeds & Northrup potentiometer.

**50. Paul potentiometer, low resistance type.** Fig. 8 is the connection diagram. It is similar to the instrument described in Par. 49 in that the lower part of the reading is obtained from an extended slide-wire on one end, and a standard-cell switch is provided at the other end. The rheostats for adjusting the battery current are within the instrument ($R$ and $r$). The slide wire is laid straight, with divisions equal to about ¼ in. (0.4 cm.), which correspond to 0.001 volt divided into 5 subdivisions. A special switch, $S$, is so arranged that the various circuits 1, 2, 3, etc., may be quickly connected to the potentiometer circuit. The resistance of the standard type is 10 ohms per volt, with a range from 0.0002 volt to 1.8 volt. It is also made with ranges as low as 0.000004 volt to 0.036 volt for thermoelectric work.

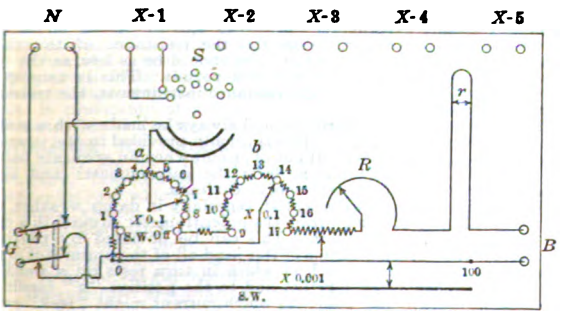

FIG. 8.—Paul potentiometer.

**51. Wolff potentiometer, high resistance type.** Fig. 9 shows the diagram of connections in the latest model. The total resistance is 20,000 ohms and there is no slide wire, all resistances being comprised in the form of 5 dials, having steps of 1,000, 100, 10, 1 and 0.1 ohm respectively. These read 0.1, 0.01, 0.001, 0.0001 and 0.00001 volt respectively. Instead of obtaining a balance by moving along the main circuit the contacts connected to "$X$," as in the slide wire form, the final balance is obtained by adding or subtracting resistance in the main circuit between these two contacts; the

Digitized by Google

three low dials are so arranged that a corresponding change is automatically made in the external part of the main circuit and the total resistance is kept constant. A separate dial is provided for the standard-cell adjustment, together with a separate resistance which can be altered to accommodate different cells without affecting the measuring circuits. The total range of the instrument is 1.9 volts.

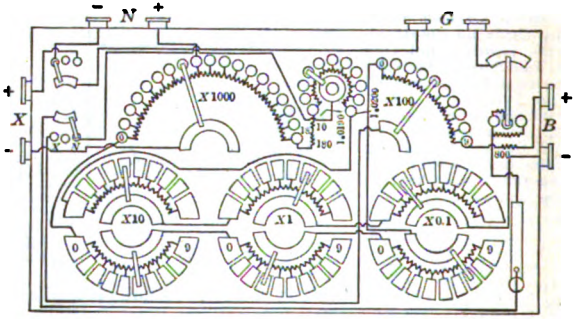

FIG. 9.—Wolff potentiometer.

**52. Care and use of potentiometers.** The following notes apply to the use of potentiometers in ordinary work.

(a) The accessories should be suitable for the particular type of instrument, that is, high or low resistance, and for the class of measurement to be made. The galvanometer should be sufficiently sensitive to give a perceptible deflection when there is an unbalance equal to the smallest scale division in the potentiometer curcuit. A low-resistance galvanometer, of the order of 100 ohms, should be used with a low-resistance potentiometer, and a high-resistance galvanometer of 500 to 1,000 or more ohms, with a high-resistance potentiometer. Similarly, the resistance of the volt box (Par. **53**) for low-resistance potentiometers should be as low as the permissible power loss in the resistance coils will permit. This is usually about 5,000 ohms for 150 volts. For high-resistance instruments, the resistance is 1,000 ohms or more per volt.

(b) The **first trials for balance** should always be made with a resistance in series with the galvanometer. This is usually provided in the instrument, with facilities for readily cutting it out of circuit when an accurate balance is being obtained. The resistance protects the galvanometer and also the standard cell from the effects of excessive currents.

(c) Trouble is sometimes experienced, especially in damp weather, due to **current "leaking to ground"** from the potentiometer circuits in a manner which produces a false deflection. This can be obviated by providing a **"guard circuit."** In one scheme of this kind all of the apparatus is placed on small, hard-rubber pillars each of which in turn rests on a small metal plate. These are connected together and to the positive "$x$" binding-post by fine bare wire. Thus all points to which current might "leak" over the surface are kept at the highest external potential to which the potentiometer is connected. When the surfaces become noticeably moist, conditions can be improved by carefully wiping with a cloth moistened with grain alcohol.

(d) **Calibration and checking.** The essential requirement is that the ratio of the resistance of each step to that resistance between the standard cell terminals shall be the same as the ratio of the corresponding potentials. For example, if the standard cell e.m.f. is 1.0183 volts and the resistance between its terminals is 101.83 ohms, the resistance of the various steps should be adjusted to 10 ohms per 0.1 volt. If the standard cell resistance is 102.848 ohms the potentiometer is still accurate if the resistance throughout the circuit is adjusted to 10.1 ohms per 0.1 volt.

Digitized by Google

**53. Volt boxes.** When the potential to be measured is greater than the range of the potentiometer (usually 1.5 volts) a volt box is used. It consists of a number of resistance coils connected in series, with taps brought out to binding posts. Fig. 10 shows the diagrammatic arrangement, in two forms. In (*A*), the potentiometer is connected to the posts marked "+" and "1.5." When the potential to be measured is between 1.5 and 15 volts, it is connected to the "+" and "15" posts, between which the resistance is just ten times that between "+" and "1.5." Hence only one-tenth of the unknown potential is applied to the potentiometer, the readings of which must therefore be multiplied by 10. Similarly, when the potential is between 15 and 150 volts, it is connected to the "+" and "150" posts, and the ratio becomes 100. In (*B*), Fig. 10, the potential to be measured is always connected to one pair of posts, designated "+" and "−," and the potentiometer connections are shifted to obtain the desired ratio. Theoretically the former method is the better because the resistance in parallel with the potentiometer is constant and the sensibility is therefore constant. In the latter case, the sensibility varies, being a minimum with the lowest ratio, or when the maximum amount of resistance is in parallel with the potentiometer. On the

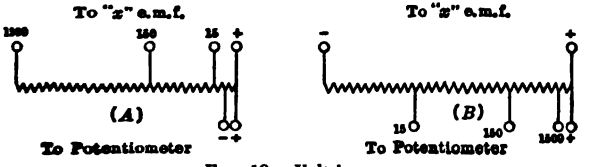

FIG. 10.—Volt boxes.

other hand, the unknown e.m.f. is always connected to a high resistance, and hence there is no danger of burning out the volt box; this occasionally happens with the first form, (*A*), due to accidental connection with the wrong terminals.

**54. Deflection potentiometers.** Precision measurements obviously can be made only with very steady sources of e.m.f. If the e.m.f. is not steady, and a higher precision than that obtainable with secondary standards (voltmeters) is desired, a deflection potentiometer may be employed. In this instrument the greater part of the e.m.f. is measured by balancing against the potentiometer current in the regular manner, and the remainder is obtained by means of the average indication of the fluctuating galvanometer, which is preferably of the portable type, The **Brooks deflection potentiometer*** is of this type.

**55. Voltmeters for continuous e.m.fs.** Indicating instruments called voltmeters are used in ordinary commercial measurements. They are, essentially, low-sensibility galvanometers provided with scales over which moves a pointer attached to the moving system. The scale is calibrated in volts by comparison with an indicating instrument of higher sensibility, or by means of a potentiometer. Practically all direct-current voltmeters employ the principle of **D'Arsonval galvanometers** as shown in Fig. 11. They consist essentially of a light rectangular coil of fine copper wire wound upon an aluminium frame, pivoted in jeweled bearings and capable of rotating in the annular space between the soft-iron core and the pole-pieces of the permanent magnet. The aluminium frame, being a closed secondary circuit, acts as a brake or damper when the coil is deflected; the instrument is thus made "dead beat." The pole-pieces are so shaped that the magnetic field strength is uniform throughout the space in which the coil moves. The field strength varies widely in different makes of instrument, ranging from 200 to 2,000 lines per square centimeter in the air gap and 1,000 to 6,000

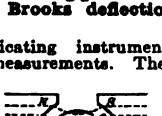

FIG. 11.—Diagram, Weston d.c. voltmeter.

* Bureau of Standards Bulletin; Vol. II, p. 225; Vol. IV, p. 275.

Digitized by Google

lines per square centimeter in the steel. A light tubular pointer attached to the coil moves over a calibrated scale. The current is introduced into the coil by two spiral springs which also provide the controlling force. Since the field strength and the gradient of the controlling forces are uniform, the deflection is strictly proportional to the current passing through the coil, and the scale divisions are uniform. A large amount of resistance is connected in series with the moving coil in order to make the current small. Thus the same instrument can be made suitable for a wide range of voltages by changing the amount of series resistance. This resistance is made of wire having a low temperature coefficient in order to neutralize as much as possible the effect of the large coefficient of the copper in the coil.

**56. Voltmeter characteristics (continuous current).** The usual **resistance** of portable voltmeters of this type varies from 50 to 150 ohms per volt and the **current sensibility** from 7 to 20 milliamperes at full-scale deflection. The resistance of the moving coils is about 75 ohms. The **torque** varies from 2 to 6 millimeter-grams at maximum current, with a **ratio of torque to weight** (in grams) of 1 to 5. The **temperature coefficient** is usually negligible, being of the order of 0.01 to 0.02 per cent per deg. cent. at full scale.

**57. Laboratory standard voltmeters (continuous current).** So-called laboratory standard voltmeters are similar to portable instruments except that they are larger, have a longer pointer, a longer and more open scale and are made with greater care. They are only semi-portable and are intended primarily for standardizing purposes.

**58. Switchboard voltmeters (continuous current)** are usually of the D'Arsonval type. The construction is the same as that of portable instruments, except that they are more substantial and rugged, especially as regards the moving system, in order to withstand the harder conditions of continuous service and excessive fluctuations. They are mounted in iron cases to protect them as much as possible from the normal stray fields due to the bus bars.

**59. Effect of stray fields.** The general effect of stray fields on the standard types of portable and switchboard instruments is shown in the table in Par. 60. These errors are usually only temporary and disappear with the stray field. When the field is very strong, as under short-circuit conditions in a neighboring conductor, **demagnetization** of the instrument magnet may result in a permanent error. Shields are likely to be of little value under such conditions because the iron becomes saturated.

**60. Effect of Stray Magnetic Fields on Continuous-current Voltmeters and Millivoltmeters**

| Stray field, lines per sq. cm.* | Error at two-thirds full-scale deflection, per cent. | |
|---|---|---|
| | Shielded | Unshielded |
| 5 | 0.5 to 1.0 | 2 |
| 10 | 0.75 to 1.75 | 3.5 to 5.5 |
| 15 | 1.0 to 3.0 | 6.0 to 7.5 |
| 20 | 1.25 to 3.25 | 7.5 to 10 |

**61. The measurement of very small continuous potentials** may be effected by some of the methods outlined in Par. **48.**

A potentiometer is most convenient, high resistance for high resistance sources such as small galvanic cells and low resistance for low resistance sources such as thermocouples.

**62. Ground detectors. Those of the direct-current type** are usually special forms of voltmeters. In one form, there are two coils, differentially wound on the moving system. One end of each coil is connected to ground and the two free ends are connected respectively to the two sides of the

* The field produced at a distance of 30 cm. (12 in.) from a conductor carrying 3,000 amp. is about 20 lines per square centimeter.

Digitized by Google

system. When there is no ground or fault on the system, the pointer stands at the centre of the scale, in normal equilibrium. When a ground or fault occurs, current flows through the coil connected to the ungrounded side, producing a deflection. In another form of detector a standard voltmeter, without the series resistance, is connected to the centre of a resistance shunted across the line, with the remaining terminal connected to ground.

## ALTERNATING-E.M.F. MEASUREMENTS

**63. Measurements of alternating e.m.f.** In alternating e. m. fs. there are three values to be considered; the maximum, the average and the "root-mean-square" or mean effective value (Sec. 2). The last value is the one usually required, being the value of the equivalent continuous e.m.f. Since the standard of e.m.f. is the standard cell, the measurement of alternating potentials involves, like continuous potentials, comparison with the standard cell. The comparison may be more or less a direct one, as in precision measurements, or it may be indirect by means of secondary standards which in turn have been standardised by direct comparison.

**64. Precision measurements of alternating e.m.f.** Obviously an alternating e.m.f. cannot be compared directly with the standard cell, the e.m.f. of which is unidirectional and constant. The comparison is made therefore by a substitution or "transfer" method. A galvanometer of the electrodynamometer type, or an electrostatic galvanometer, is connected to the alternating potential to be measured and the deflection noted. It is then connected to an adjustable continuous potential which is manipulated until exactly the same deflection is obtained. The continuous potential is then compared with the standard cell by means of a potentiometer, in the usual manner. A double-throw double-pole switch is usually arranged so that the transfer from alternating current to continuous current can be quickly made, without allowing the deflection to change appreciably, the continuous potential having been previously adjusted to about the proper value. Two readings, direct and reversed, are taken on continuous current at the same reading as the alternating deflection; the average of these two is taken as the true value, thus eliminating the effect of stray magnetic or electrostatic fields. It is obvious that, on account of this indirect method, alternating-e.m.f. measurements cannot be made with the degree of precision obtainable in measurements of continuous e.m.fs.

**65. Secondary standards.** The dynamometer type instruments which are used as secondary standards of alternating current are adapted to e.m.f. measurements by constructing the windings of a large number of turns of fine wires, instead of a few turns of heavy wires. See Par. **99**.

**66. Classification of alternating-current voltmeters.** The voltmeters in general use may be divided into five types, as follows: dynamometer, soft-iron vane, induction, hot-wire and electrostatic.

**67. Dynamometer type voltmeters** (alternating current) depend upon the reaction between a fixed and a moving coil connected in series. The

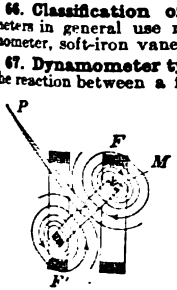

Fig. 12.—Diagram, Weston dynamometer type a.c. voltmeter.

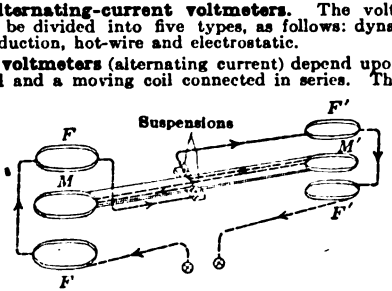

Fig. 13.—Diagram, Kelvin balance.

movement of the movable coil is a measure of the current flowing through the coils and therefore proportional to the e.m.f. impressed at the terminals. In one form (**Weston** model 18), a single coil moves within two parallel fixed

Digitized by Google

coils as shown in Fig. 12, where $F$, $F'$ are the fixed coils and $M$ is the moving coil, to which a pointer $P$ is attached. The deflection is approximately proportional to the square of the current. The scale is compressed at the upper end instead of extended because the coil moves beyond the uniform part of the field. The **Thomson Inclined Coil voltmeter** is similar, except that the plane of the fixed coils makes an angle of about 45 deg. with the shaft of the moving coil for the purpose of making the scale more uniform.

In the **Westinghouse** type $Q$, the **Kelvin balance** principle is used. This principle is shown in Fig. 13, where there are two coils, $M M'$, attached to opposite ends of a beam which is supported at the middle and free to move. Each coil moves between a pair of fixed coils, $F F$ and $F' F'$, and all of the coils are connected in series in such a manner that the moments of all the forces on the movable system, taken about the beam axis, are cumulative, thus tending to produce rotation. In the Kelvin balance the controlling or opposing force is a weight moved along a graduated scale attached to the beam supporting the movable coils; the moment of this weight about the beam axis, when the moving system is balanced, varies as the square of the e.m.f. In the Westinghouse instrument the coils are arranged vertically and the controlling force is a spiral spring. The amount of compression of this spring necessary to balance the electromagnetic forces, as indicated by a pointer moving over a scale, is a measure of the e.m.f. Single-coil instruments are direct reading and hence fluctuating e.m.fs. can be more easily read on them than on the torsionhead instruments, but the latter are astatic and therefore practically independent of stray fields.

**68. Soft-iron-vane voltmeters** (alternating current) utilise the reaction between a temporarily magnetised piece of soft iron and the magnetising field. In the **Thomson inclined coil instrument** of this type the

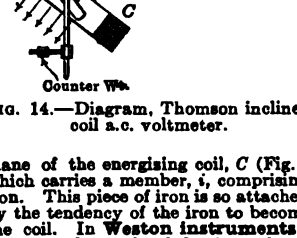

FIG. 14.—Diagram, Thomson inclined coil a.c. voltmeter.

FIG. 15.—Diagram, Weston soft-iron type a.c. voltmeter.

plane of the energising coil, $C$ (Fig. 14), makes an angle with the shaft, $S$, which carries a member, $i$, comprising a rectangular piece of very thin, soft iron. This piece of iron is so attached to the shaft that rotation is produced by the tendency of the iron to become parallel with the field established by the coil. In **Weston instruments** of this type (model 155), the reaction which produces the deflection takes place between two pieces of soft iron bent in the arc of a circle and placed concentrically, one of which, $F'$ (Fig. 15), is movable, and the other, $F$, is stationary. When the surrounding coil, $M$, is energized, the pieces of iron become magnetised in like manner, so that the resulting force is one of repulsion. The stationary piece $F$ is made triangular in shape, with the pointed end in the direction of rotation, for the purpose of making the scale more uniform. Air damping is obtained by means of a light aluminium vane, $V$, in an enclosing chamber, $C$. This type has the great advantages of low price, ruggedness, open scale and small weight.

**69. Induction-type voltmeters** (alternating current) utilise the principle of induction watt-hour meters (Par. 102), or the rotative tendency of a free cup of thin metal when placed within a so-called revolving magnetic field. Actual rotation of the movable element is prevented by an opposing spiral spring, so that the deflections become a measure of the current in the energising coils. The **Westinghouse** type P voltmeter is an important

Digitized by Google

example of this type, for which is claimed a very high ratio of torque to weight of moving element, rugged and simple construction, extremely long scale and compactness.* The arrangement of the circuits is shown in Fig. 16. The primary winding, *P*, which is connected to the line circuit, induces a current in the secondary winding, *S*, opposite in phase to the primary current. The secondary current passes through two auxiliary coils, *AA'*, wound in opposite directions on the poles. The field produced by these coils will be displaced 90 deg. in time phase from the field produced by the primary winding and approximately at right angles thereto in space, thus producing the necessary rotating field to cause the cup, *C*, to tend to rotate. Incidentally, the inherent frequency error of induction type instruments is largely neutralised by this combined transformer and induction motor action, the effect of frequency changes being opposite in the two cases.

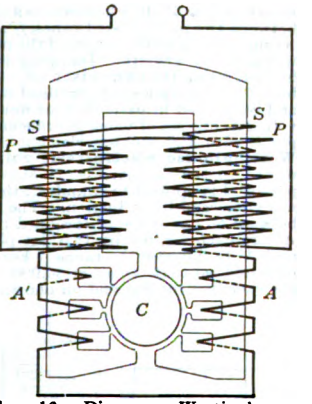

FIG. 16.—Diagram, Westinghouse induction-type a.c. voltmeter.

**70. Hot-wire voltmeters**† (alternating-current) utilise the expansion and contraction of a wire carrying a current proportional to the e.m.f. to be measured. Fig. 17 shows the principal features of the **Hartmann and Braun voltmeter.** The current flows through the platinum-silver alloy wire, *AB*, which expands under the heat produced. This expansion reduces the tension on the fine phosphor-bronze wire, *CF*, which in turn allows the silk fibre, *HE*, attached to the spring, *S*, to be pulled to the left. This fibre passes around a small pulley on the shaft of the moving system and thus produces a deflection of the pointer. Damping is effected by the aluminium disc, *D*, moving between the poles of the permanent magnet, *M*. The hot wire, *AB*, is in series with a large non-inductive resistance, *R*, so that the current is proportional to the e.m.f.

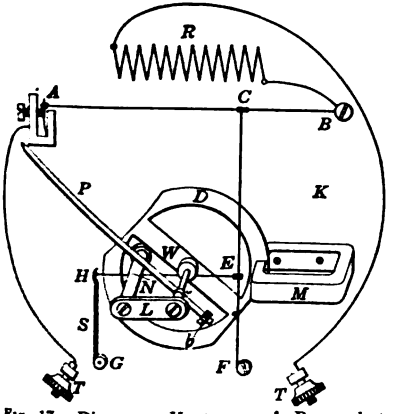

FIG. 17.—Diagram, Hartmann & Braun hot-wire type a.c. voltmeter.

**71. Electrostatic voltmeters** (alternating-current) are similar to electrostatic galvanometers (Par. 37) or electrometers, except that they are designed for measuring larger potentials and are provided

with scales which make them direct reading. They are made in a great variety of forms, for both portable and switchboard use, but are used commercially much more in Europe than in this country. The principle of their operation is shown in Fig. 18, in which $mm'$ is a thin aluminium vane suspended or pivoted between two pairs of fixed vanes, $ff'$. The deflection through moderate ranges is proportional to the square of the potential and is controlled either by a spiral spring or by gravity. Damping is produced magnetically, by air vanes, or by immersing the elements in oil. For ordinary commercial voltages a number of sets of vanes are arranged one above the other in a vertical position, and connected in parallel, thus multiplying the effect (Fig. 19). For higher voltages, one set of vanes is sufficient and they are usually placed in a vertical plane with the moving element mounted on a horizontal shaft. In the **Westinghouse electrostatic voltmeter**, the moving system is not connected to the circuit; Fig. 20 shows the arrangement of the parts. When potential is applied to $A$ and $A'$, the hollow cylinders $C$ and $C'$ become oppositely charged by induction. The resultant attraction produces a deflection because of the shape of the fixed plates, $P$ and $P'$. The condensers $K$ and $K'$ are each formed by two flat plates and are connected in series with $A$ and $A'$ to increase the range. For lower ranges these condensers are short-circuited, so that ranges of 30,000, 60,000 and 100,000 volts are available in the same instrument and on one scale. The elements are entirely immersed

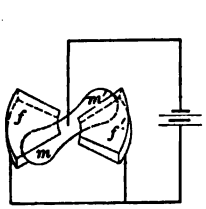

FIG. 18.—Diagram, electrostatic-type a.c. voltmeter.

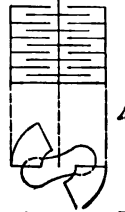

FIG. 19.—Diagram, electrostatic-type a.c. voltmeter.

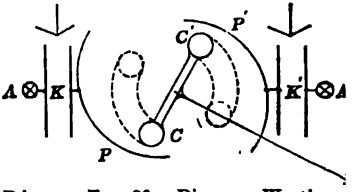

FIG. 20.—Diagram, Westinghouse high-tension voltmeter.

in oil which permits a relatively compact construction, increases the torque because of the greater specific inductive capacity of the oil and provides damping.

**72. Alternating-current switchboard voltmeters** are made in all of the types described above (Par. 66 to 70), although in this country the dynamometer, soft-iron vane and induction types are in most general use. They are similar in general to the portable instruments, due regard being given to the more severe requirements of switchboard service.

**73. Calibration of alternating-current voltmeters. The dynamometer type** of voltmeter gives the same indication on continuous current as on alternating current and may therefore be calibrated with continuous currents, direct and reversed readings being taken. The inductance in instruments of commercial ranges is so small that the readings are independent of standard frequencies.

**The soft-iron-vane type** of voltmeter should theoretically be used only on alternating current because hysteresis occurs to some degree in the vane. Practically, however, the hysteresis is so small that there is very little difference between the respective indications with increasing and decreasing potential. Provided with a steady source of e.m.f., under suitable control, these instruments may be calibrated with continuous current by taking the average of the "up" and "down" potential readings corresponding to the various points. Care should be taken that the potential is increased or decreased only to the desired value and not beyond it. Theoretically, instruments of the soft-iron type are not independent of frequency or wave-form; practically, however, the variation is not measurable throughout commercial ranges.

Digitized by Google

**Hot-wire voltmeters** are theoretically and practically independent of changes in frequency and wave form, and can therefore be calibrated with continuous current. They are especially suitable for high-frequency measurements.

**Induction-type voltmeters** are affected by changes of frequency. They must therefore be calibrated on alternating current of the frequency for which they have been adjusted, in comparison with some secondary standard which can in turn be calibrated with continuous current as described under precision measurements. Errors which result from ordinary variations in commercial wave forms are negligible.

**Electrostatic voltmeters** are independent of changes both in frequency and in wave form, and may therefore be calibrated with continuous current where the range will permit.

**74. The effect of stray fields on alternating-current voltmeters** is very marked in some types of instruments. The error will vary with the deflection and with the direction of the superposed field. In the case of unshielded, single-coil dynamometer instruments, the error caused by a magnetic stray field of five lines per square centimeter may vary from 25 per cent. at quarter scale to 5 per cent. or 10 per cent. at three-quarters scale; with a field of 10 lines per square centimeter these figures may become 75 per cent. and 25 per cent., respectively. Soft-iron-vane instruments are much less affected, a stray field of 10 lines per square centimeter causing about 10 per cent. error. Hot-wire and electrostatic instruments are not affected. Shielded dynamometer instruments are available in which the error with stray fields of 20 lines per square centimeter is only 1 or 2 per cent.

**75. Measurement of small alternating e.m.fs.** The single-coil dynamometer type voltmeter is practically the only one available for potentials of less than 25 volts. Since the deflections in this type of instrument are proportional to the square of the potential, the lowest value that can be measured with a 7.5-volt instrument is about 2.5 to 3 volts. By separately exciting the fixed coils the sensibility will be greatly increased, because the deflections will then be directly proportional to the potential impressed on the moving coil. The **"unipivot" dynamometer type** instrument (Paul) with separate binding posts for fixed and moving coils is intended to be used in this manner, full scale deflection being obtained with 1 volt.

For the accurate measurement of potentials of the order of 0.25 volt and less, dynamometer instruments must be of the suspension, reflecting type. Care should be taken that the excitation is in phase with the potential being measured and that the current through the instrument remains proportional to the potential. This current is $I = E/\sqrt{R^2+L^2\omega^2}$, wherein $E$ = impressed voltage being measured, $R$ = resistance of instrument, $L$ = inductance and $\omega = 2\pi \times$ frequency. When $R$ is large the inductance is negligible, but when it becomes small as in very low reading instruments, it may have to be considered in the measurement. In that case, the instrument can be calibrated as an ammeter on continuous current and the alternating e.m.f. computed with the above formula. For similar reasons, the temperature coefficient may become significant.

**76. Measurement of large alternating e.m.fs.** Theoretically, any alternating potential can be measured with any of the voltmeters described, if sufficient series resistance is used. In a practical sense, the large energy consumption and the insulation difficulties limit their use to measurements of a few thousand volts, and then only for testing purposes. In connection with commercial generation and transmission, potentials up to about 33,000 volts are almost universally measured in this country by means of step-down instrument transformers (shunt type) connected to ordinary voltmeters.

The measurement of potentials higher than 33,000 volts is usually required only in connection with high-voltage tests. The various methods of making such measurements are as follows:

(a) **Ratio of the step-up power transformer**, in connection with an ordinary voltmeter on the low tension side. This method requires an accurate knowledge of the transformer ratio under various conditions of load and potential, information which is often difficult to obtain.

(b) **Step-down instrument transformers** (shunt type) with an ordinary voltmeter. This method requires an accurate knowledge of the transformer ratio at various potentials, with the voltmeter as the secondary

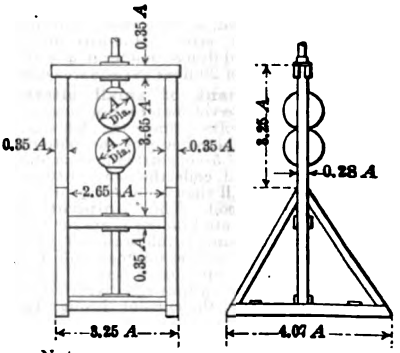
Digitized by Google

load. The method is simple, convenient and accurate, but the power consumption and the cost of the transformer become prohibitive at high potentials.

(c) **Electrostatic voltmeter.** Commercial instruments are available up to about 200,000 volts. They require no appreciable power and are quite satisfactory. The principal objections are the high cost of large sizes and the lack of dead-beat qualities.

(d) **Test coil.** Where the source of the high potential to be measured is a testing transformer, an ordinary low-reading voltmeter can be connected to a few turns of the high tension winding brought out to separate terminals. These turns should be at the grounded end of the winding. The ratio, under all conditions, will be that of these turns to the total turns in the high-tension winding, if the transformer has been well designed. This method is generally sufficiently accurate and is very convenient.

(e) **Spark gaps.** The sparking distance between two terminals in atmospheric air is a standard method of measuring high potentials. The maximum length of gap which a given potential will break down depends, in this case, on the maximum value and not upon the virtual or effective value which is the value obtained in the other methods. The maximum value, however, is the important one in tests of insulators and insulating materials. When the wave form is not a sine curve the maximum value may deviate materially from the theoretical value, which is the virtual (voltmeter reading) value multiplied by $\sqrt{2}$.



Note:
A Variation of 1 Cm. in Thickness and Width of Wood Parts is Permissible

FIG. 21.—Sphere sparks gaps.

**77. Needle-point and sphere spark gaps.** The needle-point spark has for many years been the standard method of measuring high voltages, but it is unsatisfactory for very high potentials because of variations due to atmospheric pressure, humidity, proximity of surrounding objects and sharpness of the needle-points. It has been proposed* to use spheres instead of needle-points and the 1914 A. I. E. E. Standardization Rules recommend the use of the needle gap for voltages from 10 kv. to 50 kv. and the sphere gap for voltages above 50 kv. A gap with carefully machined and polished spheres gives very reliable and consistent results due, probably, to the fact that the gap breaks down before corona forms and perhaps also to the lesser dielectric spark lag.†

**78. A. I. E. E. standard sparking distances in air, with needle-point and sphere gaps** are given in Sec. 24.

**79. Ratio of shunt-type instrument transformer.** When a very accurate measurement (within 2 per cent.) of a high potential is to be made with an instrument transformer of the shunt type, the nominal ratio cannot be relied upon as being sufficiently correct and the true ratio should be determined by a direct measurement. In the accurate measurement of power and energy the phase angle should also be known (Par. **179**). For the accurate determination of the ratio of instrument transformers of the shunt type, the following methods are typical.

(a) **Direct measurement** of the primary and the secondary voltage,

* Farnsworth, S. W. and Fortescue, C. L. "The Sphere Spark Gap," *Proc.* A. I. E. E., 1913, Vol XXXII, No. 2, p. 301. See Fig. 21.

preferably with two similar voltmeters. Fig. 22 shows diagrammatically the connections for this method. The voltmeters $V_1$ and $V_2$ are similar, and the resistance $R$ is adjusted until the two deflections are about alike. The two voltmeters are then connected in parallel on the secondary of the transformer and the indication of $V_2$, corresponding to the previous indication of $V_1$, is noted. The ratio is given by:

$$\left(\frac{R+r_v}{r_v}\right)\frac{X_1}{X_2} \tag{11}$$

wherein $R$ = resistance in series with $V_2$; $r_v$ = resistance of voltmeter $V_2$; $X_1$ = first reading of $V_2$; $X_2$ = second reading of $V_2$.

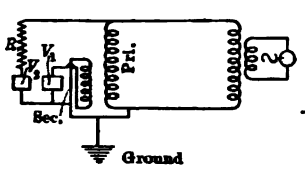

FIG. 22.—Connections—ratio of shunt type transformers.

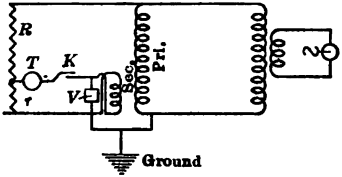

FIG. 23.—Connections—ratio of shunt type transformers.

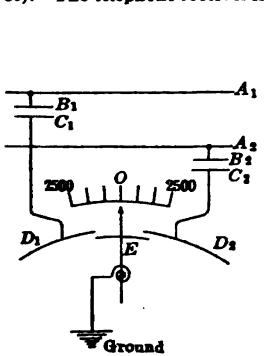
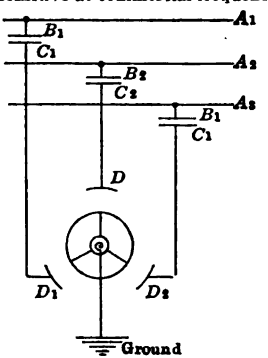
(b) **Opposition method.** The secondary voltage is reversed and connected in opposition to a part of the primary voltage, the ratio being measured in terms of two resistances. Fig. 23 shows the scheme. The resistance $r$ is varied until the detector, $T$, indicates zero or a minimum deflection. The desired ratio is evidently expressed by $(R+r)/r$.

The detector may be either a telephone receiver, a dynamometer instrument, or a synchronous reversing key with direct-current galvanometers (Par. 39). The telephone receiver is not sensitive at commercial frequencies,



Single Phase Detector



Three Phase Detector

FIG. 24.—Diagram, Westinghouse a.c. ground detector.

and if harmonics are present the precise balance point for the fundamental frequency is difficult to locate. When using a dynamometer, the fixed coils are connected in series with $R$ (not $r$) and the moving coil in place of $T$. When a rectifier is used, it is connected directly in place of $T$.

(c) **Comparison with standard transformer.** F. B. Brooks* proposes

a simple and convenient method of comparing two transformers by means of a wattmeter.

**80. Alternating-current ground detectors** are usually **electrostatic** instruments. Fig. 24 shows diagrammatically the principle of **Westinghouse detectors.** The stationary vanes are connected through condensers to the main lines, and the movable vane is connected to ground. In the single-phase detector, a charge will be induced on each end of the movable vane, opposite in sign to that on the corresponding stationary vane, setting up forces of attraction. When the system is free from grounds, these attractive forces are equal and opposed to each other; hence the moving system stands at zero. A ground on either phase wire produces an unbalanced condition and a deflection away from the grounded conductor. In the three-phase detector, the vanes are sectors of spheres, the movable vane being mounted on a universal bearing.

**81. General Electric ground detectors** operate on a principle similar to that last described. Four quadrants, or fixed, flat vanes are cross-connected and mounted between them is a moving vane connected to ground. Opposite sets of fixed vanes are connected to the two sides of the line circuit and the action is the same as described in Par. **80**. The **three-phase detector** is similar, consisting of three pairs of fixed quadrants mounted 120 deg. apart on a common base plate, and a flat moving vane with three corresponding sectors.

## CONTINUOUS-CURRENT MEASUREMENTS

**82. Absolute measurements of current.** The fundamental unit of current, as derived from the centimeter, gram and second, is defined in terms of the dimensions of the conductor and the strength of the magnetic field produced by the current. Absolute measurements of current are therefore made with instruments so carefully constructed that the current can be calculated from their dimensions.

**83. Instruments for absolute measurement of current.** Absolute determinations have usually been made with two classes of instruments. In the first, the deflection of a magnetic needle at the centre of a coil is measured, and the current is calculated from the dimensions of the coil, the strength of the earth's field and the torsion of the suspension. The best known example of this class is the tangent galvanometer (Par. **11**). This method involves, of course, any error in the determination of the earth's field. In the other class of instruments, the needle is replaced with a suspended coil. When the length and the radius of both movable and fixed coils are in the ratio of $\sqrt{3}:1$, when the centres coincide and when the dimensions of the fixed coil are large compared with those of the movable coil, it has been shown by Gray that the torque exerted by the moving system is expressed by

$$T = \frac{4\pi^2 N n r^2 I}{\sqrt{D^2+L^2}} \quad \text{(dyne-cm.)} \qquad (12)$$

where $N$ = number of turns in fixed coil, $n$ = number of turns in movable coil, $D$ = diameter of fixed coil in centimeters, $L$ = length of fixed coil in centimeters, $r$ = radius of movable coil in centimeters, and $I$ = current (coils in series). Hence by measuring the torque (weighing it), the current can be determined directly in C.G.S. units.

**84. Practical unit and standard of current.** It would be quite impracticable to make ordinary measurements in terms of the fundamental unit, by the methods indicated above (Par. **82** and **83**). The Act of Congress of 1894 which legalised certain practical units of electrical measure defined the practical unit of current, or the **international ampere**, as one-tenth of the fundamental C.G.S. unit. This Act also defined the standard unit of current as the rate of deposition of silver at the cathode of a silver voltameter (Par. **86**) constructed and operated under certain prescribed conditions, the ampere being the current which will deposit 0.001118 g. of silver per sec. in a standard voltameter.

**85. Methods of measuring continuous currents.** The several methods of measuring continuous currents may be classified as follows: voltameter; potentiometer; and ammeters.

**86. Voltameter method of current measurement.** When a continuous current is passed through an electrolyte, the latter is decomposed at

Digitized by Google

a rate which is proportional to the current strength, and an apparatus for measuring current by such means is called a voltameter. In the **silver voltameter**, the cathode or negative electrode is always platinum, the anode or positive electrode is pure silver, and the electrolyte is silver nitrate. Fig. 25 shows the general form. The anode is usually a silver rod projecting into a platinum bowl, which rests in turn on a copper plate. In cheaper forms, plates of silver and platinum are supported in a glass jar. The solution is usually about 15 per cent. (by weight) silver nitrate, and the effective area of the anode is about 50 sq. cm. per ampere. In order to prevent disintegrated silver on the anode from dropping on the cathode, the anode is surrounded with pure filter paper or a porous cup made of unglazed porcelain; in other cases, merely a shallow glass dish is placed beneath the anode. Recent investigations at the Bureau of Standards* have shown, however, that the chemical activity of filter paper results in an excessive deposit of silver and that the porous cup is much more suitable. The average current in amperes is computed from the formula

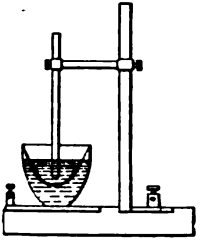

FIG. 25.—Silver voltameter.

$$I = \frac{M}{0.001118t} \quad \text{(amp.)} \qquad (13)$$

where $M$ = weight of silver deposited in grams, $t$ = total time in seconds and 0.001118 = electrochemical equivalent of silver (Sec. 19).

**87. The copper voltameter** is used to measure very large currents. The anode is electrolytically pure copper, the cathode is either copper or platinum, and the electrolyte is a solution of pure copper sulphate in the proportion of 10 g. of crystals to 40 cu. cm. distilled water. Two anodes may be used in order to utilize both sides of the cathode (Fig. 26) and the current capacity may be further increased by connecting additional plates in parallel. The current density should not exceed 1 amp. per square centimeter of cathode area.

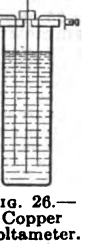

FIG. 26.—Copper voltameter.

**88. In the gas or water voltameter** the electrodes are two plates made of platinum, and the electrolyte is a 10 per cent. solution of sulphuric acid. In the electrolysis of this solution, hydrogen gas is formed at the cathode and oxygen gas at the anode. The total gas formed collects above the liquid, and is measured volumetrically in a closed graduated tube forming the upper part of the containing vessel.

**89. Potentiometer method of measuring continuous currents.** Although the silver voltameter is the legal standard for the measurement of current, its use is practically limited to reference measurements or primary standardization. It is seldom used in commercial measurements because it is much more convenient to measure current in terms of the volt and the ohm. Even in measurements of the highest precision, current is determined from the fall of potential across a standard resistance (Par. **113**), the potential being measured with a potentiometer (Par. **48** (c), **49**, **50**, **51**). The potentiometer method is not only more convenient than the voltameter method, but it is much more rapid and at least equal in accuracy, because it depends only on the measurements of a difference of potential and a resistance, both of which can be determined with a very high degree of precision.

**90. Indicating continuous-current instruments** which indicate current directly by the deflection of a pointer over a marked scale are called ammeters. Modern continuous-current ammeters are almost universally simple millivoltmeters of the D'Arsonval type connected to the terminals of a resistance (shunt) which in turn is connected in series with the main circuit whose current is to be measured. The deflections of the instrument will be proportional to the fall of potential across the shunt, and therefore to the current flowing through it. A millivoltmeter may be made an ammeter of any capacity by simply changing the resistance of the shunt.

*Bureau of Standards Bulletin, Vol. IX (1912), No. 2.

Digitized by Google

**91. D'Arsonval type of continuous-current ammeter.** The principle of these instruments has been described under "e.m.f. measurements" (Par. 55). They are usually designed to have a full scale deflection with 50 to 200 millivolts (thousandths of a volt) at the terminals. The resistance of the moving coil is much lower (0.5 to 5.0 ohms) than that of voltmeters, in order to make the millivolt constant high.

**92. Continuous-current ammeters of the switchboard type** are intended for continuous operation and the shunt loss should therefore be low. They are designed for 50 to 75 millivolts at full scale deflection. High-grade portable ammeters are designed for 100 to 200 millivolts at full scale deflection, in order to permit the use of resistance in series with the moving coil, thus reducing the temperature error, which is more important than the larger shunt loss.

**93. Shunts for continuous-current ammeters.** In switchboard ammeters and the lower grade portable ammeters of 25-amp. ratings and less, the shunt is within the instrument case. Above 25-amp. ratings, the shunt is usually separate from the instrument and means of connection are provided by special flexible leads, which are included in circuit when the instrument is calibrated, since they form a part of the resistance of the entire instrument circuit. Obviously, these leads should never be altered without recalibrating the instrument. In high-grade ammeters the shunts are separate for all capacities.

**94. Construction of ammeter shunts.** Ammeter shunts are so constructed as to have a resistance which will be constant, as nearly as possible, under all conditions. The resistance metal has a low temperature coefficient, and the temperature is kept low either by connecting several strips in parallel and making the current density low, or by making the current density high and using short lengths of the resistance metal with heavy copper terminals designed to dissipate the heat by conduction and radiation. The former method is most generally used, the strips being silver-soldered into relatively heavy copper or brass terminals which are connected into the circuit to be measured. The resistance metal should also have a low thermo e.m.f. (Sec. 2) in junctions with copper.

**95. Reduction of temperature errors in continuous-current ammeters.** Because of the large temperature coefficient of copper, it is very undesirable to connect the moving coil of the instrument directly to the shunt. Temperature errors are reduced to a negligible value by connecting sufficient resistance having a low temperature coefficient (manganin or similar metal) directly in series with the moving coil as shown in Fig. 27, or by arranging a compensating circuit as shown in Fig. 28, where $C$ = moving coil, $R_m$ = low-coefficient resistance wire, and $R_c$ = copper resistance wire.

FIG. 27.—Temperature compensation in millivoltmeters.

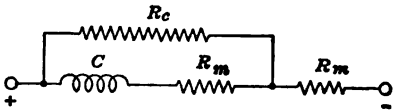

FIG. 28.—Temperature compensation in millivoltmeters.

**96. The calibration of D'Arsonval type ammeters** is effected by adjustment of the resistance of the shunt, the resistance of the millivoltmeter circuit, or both. Formerly each instrument and shunt were adjusted together, but it is becoming customary to adjust all of the instruments of a given type to deflect full scale with the same potential in millivolts at the terminals. The shunts for these instruments are all similarly adjusted to give the same potential drop, thus making all shunts and instruments of a given type interchangeable. The shunts should be adjusted by varying the main-line resistance between the potential taps and not by adjusting resistance wire connected in series with the instrument leads. In calibrating switchboard instruments and the lower grade portable instruments, the potential terminals are attached to the main current terminals and adjust-

Digitized by Google

ment is effected by reducing the cross-section of the resistance strips which has been purposely left too large. In instruments of higher grade, the potential terminals are connected to the resistance strips inside the main terminals; approximate adjustment is obtained by trial, and after soldering the tap wire to the resistance strip, final adjustment is obtained by varying the cross-section, or by cutting back a tongue-shaped piece of the strip whose end is soldered to the tap wire.

## ALTERNATING-CURRENT MEASUREMENTS

**97. Measurements of alternating currents.** There are, in the case of alternating currents, three values to consider, the maximum, the average and the mean effective or root-mean-square; the last is the value usually desired. Alternating currents, like alternating e.m.fs., can only be compared with the standard by means of a "transfer" instrument, that is, one in which the effect produced by a current is the same whether the current is continuous or alternating. Having determined the indication produced by the alternating current to be measured, the value of a continuous current which will produce the same deflection is obtained in terms of the standard.

**98. Precision measurements** of alternating current are made with "transfer" instruments (Par. **64**) which are usually of the reflecting, suspension, electrodynamometer class. The principle of these instruments is described in Par. **32** to **34**. P. G. Agnew has developed a tubular water-cooled electrodynamometer having a capacity of 5,000 amperes and an accuracy of 0.05 per cent.*

**99. Secondary standards for alternating-current measurements,** adapted for direct observation, must obviously be capable of calibration on continuous current. There are several instruments which fulfil this requirement.

The **Siemens electrodynamometer** consists of two stationary coils connected in series, with a moving coil suspended between them by a silk fibre. The deflecting force or moment is opposed by a spiral spring, which is twisted by hand (in the so-called **torsion head**) until the moving coil is brought back to the zero position. The amount of this twist, as indicated on a scale over which moves a pointer attached to the torsion head, is a measure of the current. The final relation of the fixed and moving coils is therefore always the same. The current in amperes is $I = k\sqrt{L}$, where $L$ = twist of torsion head in degrees and $k$ = a constant determined by calibration on continuous current. The instrument is sensitive to stray fields, from both direct and alternating current. The presence of such fields can be detected by passing current through the moving coil only; a deflection under such conditions indicates a stray field. Its effect may be reduced to a negligible quantity by turning the whole instrument until no deflection is noted.

**100. The Kelvin balance** (Par. **67**) is an electrodynamometer type of instrument which is astatic and in which the forces of attraction and repulsion are actually weighed as in an ordinary balance. Kelvin current balances are troublesome to use unless the current is extremely steady, a condition which rarely exists with alternating currents; they have therefore been practically superseded, in this country at least, by other and more reliable, convenient instruments of the dynamometer type, of which the Westinghouse "precision" ammeter is an example.

**The Westinghouse "precision" ammeter** is practically a Kelvin balance, of relatively small dimensions, in a vertical instead of a horizontal plane. The electromagnetic forces are opposed by a helical spring which is twisted by means of a torsion head as in the Siemens dynamometer. The angular movement of the torsion head necessary to keep the moving system in the zero position is a measure of the current. The actual value of the current is equal to the square root of the deflection, multiplied by a constant.

**101. Types of alternating-current ammeters.** The four principal types of commercial ammeters are as follows: dynamometer, soft-iron vane, induction, and hot wire. They are similar to the voltmeters of the same types (Par. **67** to **70**), except that the windings consist of relatively few turns of

* Agnew, P. G. "A Tubular Electrodynamometer for Heavy Currents." Reprint No. 184, Bureau of Standards, June 17, 1912.

Digitized by Google

coarse wire instead of a large number of turns of fine wire, the ampere-turns being about the same in both cases. Hot-wire ammeters with ratings of more than 1 or 2 amp. are usually small current instruments connected to non-inductive shunts, as already described in principle (Par. 90).

**102. Measurements of large alternating currents.** The only type of ammeter which is generally used in the direct measurement of large alternating currents is the hot-wire ammeter, because it can be used with shunts. While shunts are made for capacities of 1,000 amp. and over, the accuracy with shunts of very large capacity depends upon the care taken in the design to eliminate the eddy-current and skin-effect errors. The most common method is to use current transformers of the series type, to step down the current to a small value, usually 5 amp., which is convenient to measure with standard instruments.

**103. Series-type instrument transformers** (also known as current transformers) serve two purposes; the convenient measurement of large currents, and the insulation of instruments and apparatus from high-voltage circuits. They are similar to so-called power transformers, except that the latter are connected in shunt across the line and the secondary potential remains substantially constant irrespective of the connected load. Series transformers are connected in series with the primary line, and the secondary current remains substantially constant for a wide range of loads. The load consists of instruments or other devices which are connected directly in series with the secondary winding.

**104. Measurement of ratio of series transformers.** The ratio of series-type instrument transformers may be determined by measuring the primary and secondary currents directly with current-measuring instruments, but obviously such a method is much less accurate than null or "zero" methods. The principle of the latter is the same as that of the potentiometer. A non-inductive resistance in the secondary circuit is adjusted until the potential drop across it is equal to that in a non-inductive resistance in the primary circuit. The ratio of the two resistances is equal to the ratio of transformation. The differences among the various null methods are largely in the manner of determining the balance and in measuring the phase angle. Fig. 29 shows the scheme of a method used at the Bureau of Standards,* where a reflecting dynamometer is used as the detecting instrument. $R^1$ and $R^2$ are the resistances in the primary and secondary circuits, respectively. The fixed coil of a dynamometer, $D_1$, is connected in series with the primary; then, with the switch $S$ thrown to the right, $R_2$ is adjusted until zero deflection is obtained. The component of the potential drop in $R_2$, which is in phase with that in $R_1$, is thus equal in magnitude to the drop in $R'$. Since the phase angle is always very small, the ratio of $R_2$ to $R_1$ may be taken as the transformer ratio. The phase angle is then determined by measuring the component of the $R_2$ drop which is 90 deg. from the $R_1$ drop, by means of another dynamometer, $D_2$, the fixed coils of which are excited by a current displaced 90 deg. in phase from the primary current.

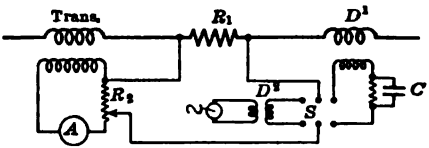

FIG. 29.—Connections for measuring ratio of series type transformers.

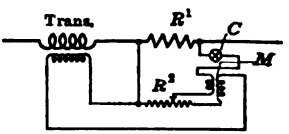

FIG. 30.—Connections for measuring ratio of series type transformers.

Fig. 30 shows the scheme of a method used at the Electrical Testing Laboratories.† $R_1$ and $R_2$ are the primary and secondary resistances,

Digitized by Google

respectively, and $C$ is the detector which in this case is a synchronously driven reversing key (Par. **38**) connected to a Paul "unipivot" galvanometer. The secondary of a mutual inductance, $M$, is in the detector circuit and the primary of the inductance is in series with the secondary circuit of the transformer. After the value of $R_2$ has been found which will make the "in-phase" potential drops balance each other, the quadrature drop in $R_2$ is balanced by the e.m.f. in the secondary of the variable mutual inductance. Knowing the value of this inductance, the value of the phase angle may be calculated.

**166. Ratio of series-type instrument transformers.** Theoretically, the ratio of transformation should be the same as the ratio of the secondary turns to the primary turns, and the secondary current should be in exact phase opposition to the primary current. Actually neither of these conditions exists because of the current required to excite the core and supply the losses.

In many commercial measurements these errors can be neglected, but in accurate measurements of current, power and energy, the true ratio should be known. In power and energy measurements, the phase angle (angle between the actual vector position of the secondary current and the theoretical position which is 180 deg. from the primary current) should also be known. See Par. **179**.

**166. Measurements of small alternating currents.** The methods described for measuring small alternating e.m.fs. (Par. **75**) may be used for similar measurements of current. Portable ammeters of the soft-iron-vane type are made with ratings as low as 50 or 75 milliamperes at full scale; the impedance of such instruments is much higher than that of dynamometer instruments. The dynamometer type, when separately excited, can be used to measure currents as low as 10 milliamperes, with fair accuracy; one form made by Paul has a maximum range of 20 milliamperes. For very small currents, reflecting dynamometers are the most suitable.

**167. Measurements of high-frequency alternating currents.** High-frequency currents are best measured by methods involving the heating effect of the current. In the Fleming thermoelectric ammeter for relatively **large currents** the high-frequency current flows through a number of very fine copper wires stretched between the two terminals. These wires are separated in space and each carries about 2.5 amp., additional wires being added up

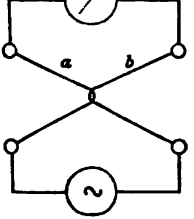

FIG. 31.—Diagram, Paul high-frequency galvanometer.

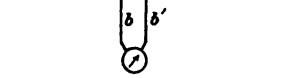

FIG. 32.—Diagram, high-frequency ammeter.

to 30 amp. of total capacity. At the middle of the centre wire is placed a thermojunction connected to a sensitive galvanometer, whose indications are proportional to the mean effective value of the high-frequency current. For instruments used in Radiotelegraphy see Sec. 21.

**Small high-frequency currents** are sometimes measured with the thermogalvanometer described in Par. **36**. In a high-frequency galvanometer made by Paul, Fig. 31, a thermojunction may be formed with an iron wire, $a$, and a eureka wire, $b$, looped together in such a way that the high-frequency current traverses the junction from one side while a sensitive galvanometer is connected to the other. Similar instruments in which the measured current does not flow through the joint are stated to be superior because of the absence of the Peltier effect* (Sec. 2).

* Douse, C. M. *The Electrician*, London; Aug. 19, 1910; p. 765.

Digitized by Google

Another practical method of measuring small high-frequency currents is indicated in Fig. 32, where $a$ and $a'$ are two fine wires of different materials stretched between two terminals. The wires leading to the galvanometer are of the same materials, but so connected that $a'$ and $b$ are alike, and $a$ and $b'$ are alike. Thus there are two thermocouples in series. Obviously the connections should be at the same potential, and this is adjusted on continuous current with direct and reversed readings. In a bridge method, the current is measured by the change in resistance of a carbon lamp (with a very small filament) in one arm of a bridge, Fig. 33; inductance coils, $a$ and $a'$ prevent the high-frequency current from flowing through the bridge.

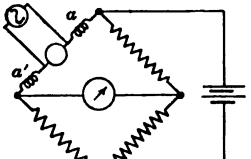

FIG. 33.—High frequency current measurements—bridge method.

**108. Measurement of rectifier currents.** Either of two values of the current from a rectifier may be required, the average value, or the root-mean-square value. In connection with storage-battery charging, the average value corresponds to the equivalent c.c. value and a permanent-magnet type of measuring instrument should be used. On the other hand, the power taken by incandescent lamps varies as the square of the current, and the equivalent c.c. current should be measured with instruments which indicate the mean effective value such as hot-wire or dynamometer ammeters.

**109. Measurements of telephone currents.** Telephone currents may be measured with a form of potentiometer* or with a barretter (Par. **40**) but since telephone currents are of constantly varying amplitude and frequency, measurements made by this and the above methods are usually of little value. Telephonic intensities are usually compared by ear with a telephone, using artificial standardized cables. Where quantitative measurements are required, a high-sensibility oscillograph can be used.†

## RESISTANCE MEASUREMENTS

**110. Resistance standards in general.** The practical unit of resistance, the **ohm**, is represented by a column of mercury having certain dimensions (Sec. 1). This standard is obviously difficult to construct, maintain and use; and, in general, will be found only in the laboratories of the national custodians of the fundamental electrical standards.

**Secondary standards** are therefore employed in actual measurements. These are made with metal of high specific resistance, in the form of wire or ribbon. Manganin (a copper-nickel-manganese alloy) is most used, because, when properly treated and aged, it meets the necessary requirements. These requirements are: permanent electrical and physical characteristics; low thermo e.m.f. in junctions with copper; small temperature coefficient of resistance; and relatively high specific resistance. The completed standard must, in addition, be unaffected by immersion in oil, or by changes in atmospheric conditions.

**111. Classes of resistance standards.** In general, resistance standards may be divided into two classes; standards of resistance, or those used primarily for the measurement of resistance; and current standards, or those intended primarily for the measurement of current.

**112. General construction of standards of resistance.** Standards of resistance have very small current capacity. They are made in two forms, the **Reichsanstalt** and the **N.B.S.** (National Bureau of Standards).‡ The former is shown, partially in section, in Fig. 34. The N.B.S. form is shown in Fig. 35. The distinctive features of the latter form are that it is immersed in oil and hermetically sealed. This prevents the absorption of moisture by

the shellac and the consequent expansion of the fine wire used in the larger resistances.* Both forms are intended to be hung from mercury cups by means of lugs, and suspended in an oil bath in order to measure the temperature more accurately. The N.B.S. form is made only in sizes larger than 1 ohm.

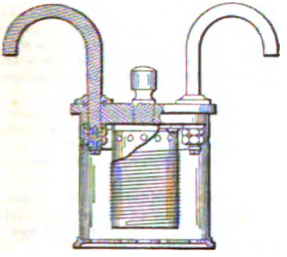

FIG. 34.—Standard resistance—Reichsanstalt form.

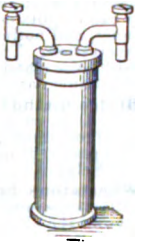

FIG. 35.—Standard resistance—N.B.S. form.

**113. Current standards are made in two forms,** the **Reichsanstalt** and **air-cooled.** The Reichsanstalt standards are made in two types, the small pattern for moderate currents, and the large pattern (in low resistances) for large currents. The small-pattern form is similar in appearance to Fig. 34 except that for 1 ohm and less, separate potential taps are provided. They are suspended from mercury cups in an oil bath for cooling purposes.

The current ratings assigned by Otto Wolff and the Leeds and Northrup Company to small-pattern, Reichsanstalt form of standards are as follows: When used for resistance measurements 0.3 and 1.0 watt, for still-air-cooling and oil-cooling respectively. When used for current measurements with a temperature rise of 10 deg. cent., 2.5 and 10 watts for still-air-cooling and oil-cooling respectively. Large-pattern low-resistance current standards have capacities from 100 watts to 2,500 watts and over.

**114. Air-cooled current standards** employ sufficient material to permit of use in air without excessive temperature rise. While they are not as accurate or as reliable as the Reichsanstalt form, they are amply satisfactory for much commercial work, especially where oil baths would be inconvenient. Fig. 36 shows a Leeds and Northrup Co. resistance, of 0.00002 ohm, and 2,000 amp. capacity, for which an accuracy of 0.04 per cent. is claimed.

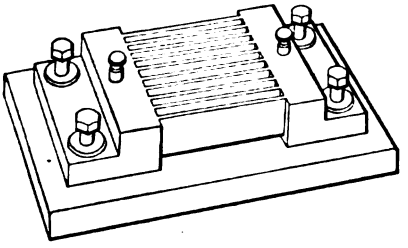

FIG. 36.—Leeds & Northrup air-cooled standard resistance.

**115. Measurements of conductor resistance.** There is no sharp distinction between materials commonly called conductors and those called insulators. Resistances of the former class may, however, be relatively high or relatively low, and certain methods of measurement are especially applicable to each class.

**116. The fall-of-potential method** consists simply in noting the voltage drop with a known current flowing through the resistance, and calculating the resistance from Ohm's law, $R = E/I$. This method is not suitable for

* Bureau of Standards Bulletin, Vol. IV, 1907, p. 121.

Digitized by Google

very high or very low resistances and the accuracy depends upon the measurement of two unknown quantities with indicating instruments. Furthermore the current required to give a readable drop may cause overheating. The method should therefore be used with caution and only where accuracy is subordinate to simplicity and convenience. The potential should be measured, when possible, between points well within the current connections, especially when the resistance is low and the current is high. Greater accuracy can be obtained by substituting a standard resistance in place of the ammeter, and noting the drop across it, and across the unknown resistance, in succession. The latter is then equal to the ratio of the two readings multiplied by the standard resistance. The accuracy will be greatest when the two resistances are nearly equal.

**117. Bridge methods** are the most accurate for resistance measurements because: (a) they are zero methods; (b) comparison is made directly with standardized resistances, the accuracy of which can be made very high. The principal types of bridges are known as Wheatstone, slide-wire, Carey-Foster and Kelvin.

**118. Wheatstone bridge.** The Wheatstone bridge is most generally used for the measurement of all but the highest and the lowest resistances. Fig. 37 shows the theoretical arrangement of a Wheatstone bridge where $r$, $r_1$, and $r_2$ are accurately known resistances and $r_x$ is the resistance to be measured. When using the bridge, the various resistances are adjusted until the galvanometer, $G$, shows no current flowing;

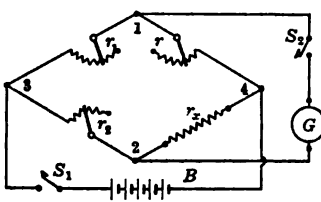

FIG. 37.—Diagram of Wheatstone bridge.

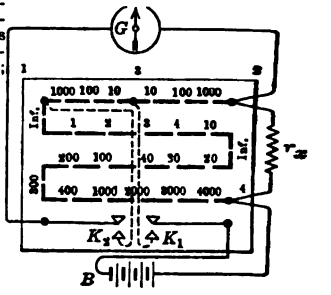

FIG. 38.—Wheatstone bridge—Postoffice form.

then, $r_x = (r_1/r_1)r$. The battery switch, $S_1$, should always be closed before the galvanometer switch, $S_2$, in order to protect the galvanometer from the momentary rush of current. The galvanometer and the battery may be interchanged without affecting the result (Sec. 2, Par. 30).

**119. Forms of Wheatstone bridges.** These bridges are made in a variety of forms. In most forms the resistances, $r$, $r_1$ and $r_2$, consist of a number of resistance coils or units carefully adjusted to various multiples of 10 and so arranged that they can be conveniently connected in and out of the circuit by means of plugs or switches. The resistances, $r_1$ and $r_2$ (Fig. 37) are commonly called the ratio arms and $r$ the rheostat arm. A very early form, which is still in use in small portable sets, is the **Postoffice** pattern, shown diagrammatically in Fig. 38. Coils are cut out by short-circuiting them with plugs, so that there may be several plug-contact resistances of an unknown and variable amount in a given arm. In the **Anthony** form, shown diagrammatically in Fig. 39, this objection is overcome by arranging the coils of the rheostat arm on the "decade" plan in which there are nine 1-ohm coils in the "units" division, nine 10-ohm coils in the "tens" division, etc. Any number of coils in a given division can be connected in circuit by changing only one plug. In many later types, the ratio-arm coils are also connected on the decade plan, which in addition to eliminating plug-contact resistance errors, permits interchecking the coils. Furthermore, the decade arrangement permits the use of sliding-brush or dial construction instead of plugs.

Digitized by Google

**120. Use of Wheatstone Bridges.** Such bridges are best suited for measuring resistances of the order of about 1 ohm to 100,000 ohms. Accuracies of the order of 0.05 per cent. are obtainable with a first-class bridge if the unknown resistance is intermediate in value between the limits last named. The maximum precision is obtained when the four arms are equal; hence this condition should always be approached as nearly as possible by keeping $r_2/r_1$ small, and $r_3$ and $r_1$ as nearly equal to $r$ as convenient. A galvanometer with 100 ohms to 500 ohms resistance will be satisfactory for nearly all classes of work. The resistance coils will dissipate about 1 watt without overheating, but care should be taken that the current does not become excessive when the ratio becomes large.

**121. The slide-wire bridge** is one of the earliest forms of the Wheatstone bridge. It is convenient and rapid where many similar measurements are to be made. It differs from the standard Wheatstone bridge in the respect that balance is obtained by varying the ratio $r_2/r_1$ instead of the resistance $r$ (Fig. 37). This is accomplished by moving the contact, $b$, Fig. 40, along a wire, $ac$, which forms the resistance $r_1 + r_2$. This wire should be uniform in cross-section and homogeneous, so that the resistance per unit length will be constant. At exact balance, the ratio of the lengths $bc/ab = r_2/r_1$; and $r_x = (r_2/r_1)r$, as before. The precision is a maximum when the sliding contact is at the centre. When the slide wire is short, the precision decreases rapidly with settings toward either end. The length may be increased, in effect, by inserting equal resistances at $n$, $n'$, which increases the sensibility, but also decreases the permissible difference between $r$ and $r_x$.

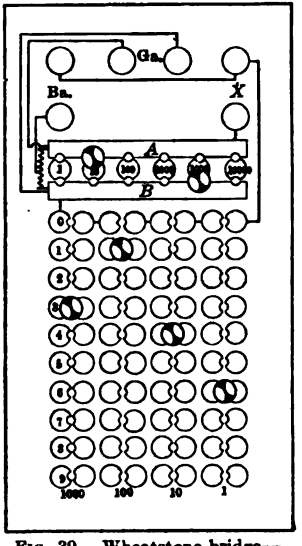

FIG. 39.—Wheatstone bridge—Anthony "decade" form.

**122. The Carey-Foster bridge** is particularly adapted to the comparison of low resistances. The distinctive feature is the elimination of the contact resistance and other unknown resistances, in the arrangement shown in Fig. 40, by taking two readings. The bridge is first balanced with the contact at $x$. The resistances $r$ and $r_x$ are next interchanged and a balance obtained at $x_1$. If the resistance of the slide wire per unit length is $\rho$, then $r_x - r = \rho(x_1 - x)$. This method is especially suitable for comparison of standard resistances with each other and for temperature coefficient determinations.

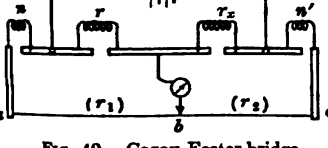

FIG. 40.—Carey-Foster bridge.

**123. The Kelvin double-bridge** is especially suitable for measurements of low resistances. It is the most generally used form, even in the most precise work, because of its accuracy and convenience. The principle is shown in Fig. 41. The resistance of the connection between $r$ and $r_x$ is made negligibly small and the bridge assumes the form of the Wheatstone bridge (Fig. 37) with the addition of an extra pair of ratio arms, $\alpha$ and $\beta$. When a balance is obtained:

$$\frac{r_x}{r} = \frac{r_1}{r_2} + \frac{d}{r}\left(\frac{\beta}{\alpha+\beta+d}\right)\left(\frac{r_1}{r_2} - \frac{\alpha}{\beta}\right) \qquad (14)$$

Digitized by Google

In practice, $r_1/r_2$ is kept equal to $\alpha/\beta$ and the resistance $d$ is made negligibly small. Then $r_x = r_3 r/r_1$, as in the Wheatstone bridge.

In the Wolff bridge, Fig. 42, the ratios $r_1/r_2$ and $\alpha/\beta$ are automatically adjusted simultaneously, by sliding contacts on the four dials. In the Leeds and Northrup bridge, Fig. 43, both $r$ and the ratio $r_1/r_2$ are adjusted.

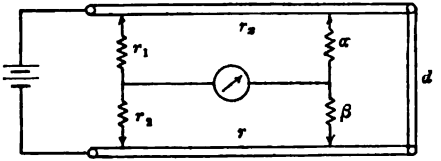

FIG. 41.—Diagram of Kelvin double bridge.

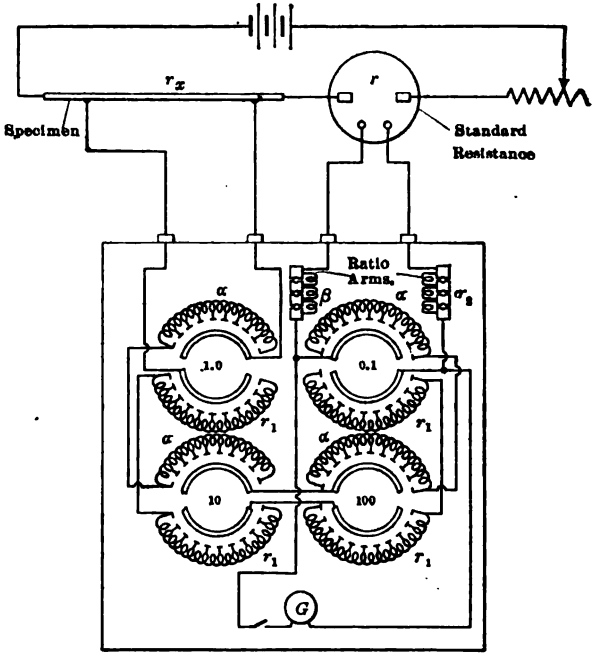

FIG. 42.—Kelvin double bridge—Wolff form.

**124. Conductivity measurements.** The specific conductance or conductivity of a material is the reciprocal of the specific resistance or resistivity. The relative conductivity is the ratio, expressed in per cent., of the specific conductance of the sample to that of a standard material. The relative conductivity may be based on equal masses or equal volumes. The former is in most common use because conductor metals are usually sold on a weight basis (see Sec. 4).

Digitized by Google

**125. Conductivity standards.** The present official standard of the A. I. E. E. is the **International Annealed Copper Standard,*** defined as follows:

**Mass-resistivity** at 20 deg. cent.:
0.15328 ohm (meter, gram)
875.20 ohms (mile, pound)

**Volume-resistivity** at 20 deg. cent. and 8.89 density:
1.7241 microhms (cm.³)
0.67879 microhms (in.³)
10.371 ohms (mil, foot)

For earlier standards of copper resistivity, see Sec. 4.

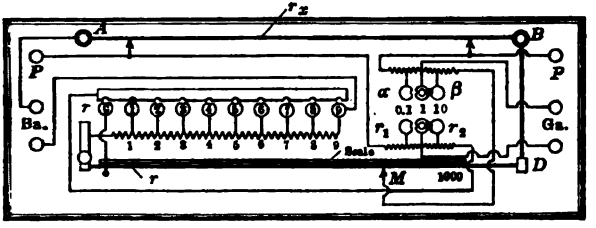

FIG. 43.—Kelvin double bridge—Leeds & Northrup form.

**126. Methods of measuring conductivity.** Conductivity may be determined by calculation from the measured resistance or by direct comparison with standards of conductivity. When the conductivity is to be calculated from the resistance, the specimen must have a uniform cross-section. The resistance of a definite length is carefully determined, the temperature being noted. Then the resistance of a piece of copper having 100 per cent. conductivity and the same weight and length as the specimen (or, for volume basis, the same cross-section and length) is calculated from the stated definition of the standards. The ratio of these two resistances is the conductivity of the specimen. The direct comparison methods employ conductivity bridges which are adaptations of the Kelvin bridge. They are intended for commercial work, where speed combined with moderate accuracy is important.

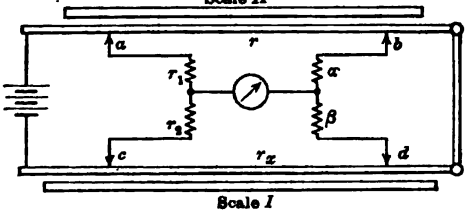

Fig. 43a.—Diagram, Eoope's conductivity bridge.

**127. In the Hoope's conductivity bridge,†** the conductivity of a specimen of wire is read directly from a graduated scale. The principle is shown in Fig. 43a where $r_x$ is the specimen to be measured, $r$ a standardized wire and

$r_1$ $r_2$ $\alpha$, $\beta$, are the double ratio coil. All four of the latter are made equal.

Digitized by Google

about 300 ohms each, in order to eliminate the effect of contact resistance at $a$, $b$, $c$ and $d$. When the bridge is balanced, the resistance between $c$ and $d$ on $r_x$ is equal to that between $a$ and $b$ on $r$. The unknown specimen $r_x$ is cut to a certain definite length and carefully weighed. The contact, $b$, on the standard is then set at the point indicated on the carefully graduated scale $H$, which corresponds to this weight. Then the resistance, $ab$, is equal to that of a piece of wire having 100 per cent. conductivity, a length equal to 100 parts in the scale $I$ and the same weight per unit length as $r_x$. Contact $d$ is shifted until a balance is obtained and the conductivity is read directly from scale $I$, 100 scale divisions corresponding to 100 per cent. conductivity. One standard is provided for every three sizes of wire in the American (B. & S.) gage. The standards are usually of the same material as that being tested, so that the temperature does not have to be observed.

**128. Resistance of rail joints.** The testing of rail bonds consists in determining, either, (a) the ratio of the resistance of a given length of rail, including a bonded joint, to that of the same length of continuous rail; or (b) the length of solid rail which has the same resistance as the joint. The resistance of rail bonds is usually expressed in the latter manner, whether measured in that way or by the former method. Three methods are employed: millivoltmeter, bridge, and opposition.

**129. Millivoltmeter method of measuring rail bonds.** In the millivoltmeter method, simultaneous readings are taken with 2 millivoltmeters, one connected across the bond and the other across a definite length of rail. If the current fluctuations are not too rapid, only one instrument is necessary, provided there is a suitable arrangement of keys to change the connections in quick succession.

**130. In the Roller bond tester** the principle of the **slide wire form of Wheatstone bridge** is employed (Fig. 44). Balance is obtained by moving the contact $B$ back and forth. At balance, $ab/bc = (r_1+m)/(r_2+n)$; where $ab$ = resistance of bond and $bc$ = resistance of the standard length of rail. The resistances $r_1$ and $r_2$ have the effect of extending the slide wire and providing greater accuracy (see Par. **121**). In the actual instrument, the slide wire takes the form of a circle and the scale is graduated to give the resistance directly in terms of the number of feet of the solid rail being tested.

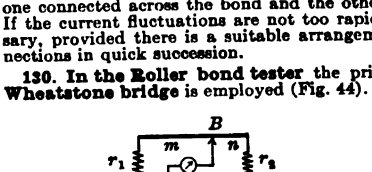

FIG. 44.—Diagram, Roller bond tester.

**131. The Conant bond tester** is an example of the class in which the drop across the joint is opposed to that across a length of solid rail, the outer contact on the latter ($c$, Fig. 44) being moved along until the two potentials are just equal and opposite. The detector is a telephone receiver in series with a make and break device operated by a clock.

**132. Insulation resistance.** The resistance of insulating materials is usually measured by deflection methods. In the case of resistances of the order of 1 megohm and less, a Wheatstone bridge may be used, but the accuracy will be low because of the extreme ratio required (Par. **121**) and the low insulation resistance of the bridge.

Two general classes of deflection methods are used: (1) direct deflection and (2) leakage. The direct-deflection methods involve a simple application of Ohm's law, the current being measured with a voltmeter used as an ammeter or with a galvanometer.

**133. Direct-deflection method (insulation resistance).** When the resistance is of the order of 1 megohm, an ordinary voltmeter will give results which are sufficiently accurate for most purposes. Two readings are taken, one with the voltmeter directly across the battery or generator, and the other with the resistance to be measured connected in series with the voltmeter. The resistance is $R = r_v(d-d_1)/d_1$; where $r_v$ =

Digitized by Google

resistance of voltmeter (the greater the resistance per volt, the higher the precision), $d$ = deflection of voltmeter in first reading, $d_1$ = deflection in second reading. Obviously a portable galvanometer with series resistance may be used as a voltmeter.

**When the resistance is moderately high,** a high-resistance reflecting D'Arsonval galvanometer is employed. Fig. 45 shows the diagrammatic arrangement for measuring the insulation of a cable. The measurement is made as follows: after the galvanometer shunt, $s$, is set at the highest value (Par. **29** and **30**) and $r_s$ is short-circuited, the main circuit is closed. The shunt is then decreased until the largest readable deflection is obtained. A reading is taken after 1 min. This procedure is then repeated with the standard resistance $r_s$ (usually 0.1 or 1 megohm) in circuit and the specimen short-circuited. The resistance of the specimen in megohms is: $R = G/d_1 s$; where $d_1$ = first reading, $s$ = multiplier corresponding to the shunt setting

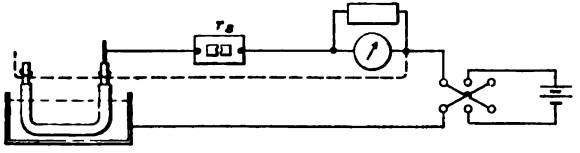

FIG. 45.—Diagram, insulation resistance of cable.

(that is, 1, 10, 100, 1,000 or 10,000) and $G$ = galvanometer megohm-constant (Par. **24**) as obtained from the second measurement. The constant is $G = ds r_s$; where $d$ = deflection, $s$ = shunt multiplier, $r_s$ = standard resistance in megohms.

**134. Leakage method of measuring insulation resistance.** Very high resistances such as the resistance of porcelain and glass, and surface leakage resistance of line insulators, are best measured by the method of leakage, also known as the loss-of-charge method. This method is based on the theory that if the insulation resistance of a condenser is infinite, it will retain a charge indefinitely; whereas if the resistance between the condenser terminals (either the internal resistance or a resistance connected externally) is finite, the rate of loss of the charge (or leakage) will be a measure of that resistance. The principle of this method is shown in Fig. 46 where the resistance to be measured, $r$, is connected in parallel with a condenser $C$. Key $a$ is closed and immediately opened, thus charging the condenser. Key $b$ is closed immediately after $a$ is opened and the deflection, $d_1$, of the ballistic galvanometer noted. The process is repeated, $a$ being left open a definite time, $t$ seconds, before $b$ is closed and a second deflection $d_2$ observed. The resistance in megohms is then:

$$r = \frac{t}{2.303\, C \log_{10}\left(\frac{d_1}{d_2}\right)} \quad \text{(megohms)} \qquad (15)$$

where $C$ is the capacity of the condenser in micro-farads.

The insulation resistance of the condenser is usually not infinite. Correction should be made by measuring the resistance of the condenser in a similar manner, $r$ being disconnected. If $r_2$ is the resistance of the condenser and $r_1$ the resistance obtained above in Eq. 15, the corrected value is

$$r^1 = \frac{r_1 r_2}{r_2 - r_1} \quad \text{(megohms)} \qquad (16)$$

**135. Measurement of specific resistance (resistivity) of solid insulating materials.** This is obtained by calculation from the resistance between two similar metallic electrodes of known area in intimate contact with the opposite and parallel faces of a specimen of the material. Tin-foil makes convenient and satisfactory electrodes if backed with blotting paper and sufficient weight to insure good contact.

**136. The specific resistance of liquid insulating materials** may be approximately determined by pouring a specimen into a round glass cylinder

Digitized by Google

or graduate in which two circular, closely fitting disc electrodes are supported. One of the electrodes should be movable so that the resistance of columns of several different lengths can be measured. The first measurement should be taken as the zero or base reading and the results checked by calculation of the increase in resistance and the corresponding increase in the spacing of the electrodes at different settings.

**137. Precautions in measuring insulation resistance.** In the measurement of the insulation resistance of specimens having electrostatic capacity, sufficient time should be allowed for the specimen to become charged, that is, until the deflection becomes constant, at a minimum value. This usually takes place within 1 min., except in long lengths of cable. In order to eliminate uncertainties in this connection, it is customary to specify 1-minute "electrification."

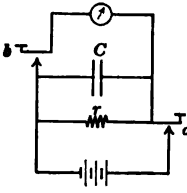

FIG. 46.—Leakage method of measuring insulation resistance.

As the apparent insulation resistance varies with the testing potential, one hundred volts is usually prescribed as the minimum pressure that should be used.

Leakage over the surface of wire or other specimens may be a source of much trouble in damp weather. In wires and cables, the lead or braid should be removed for 2 or 3 in. from the ends and the exposed insulation coated with hot, clean paraffine; or, just before measuring, these prepared ends may be carefully dried with an alcohol, Bunsen or other flame free from carbon. As a further precaution, a "*guard*" *circuit* may be arranged as shown by the dotted lines in Fig. 45. This consists of a few turns of fine copper wire twisted around the insulation close to the copper conductor and connected to the battery side of the galvanometer. In the case of solid specimens, the twisted wire is replaced with a ring of tin-foil as shown in Fig. 97.

**Specimens having electrostatic capacity** should be put in a neutral condition by rapidly reversing the current a number of times, beginning at a low rate of reversals and gradually increasing. Where the capacity is high it may be advisable gradually to decrease the applied voltage at the same time.

The side of the circuit which contains the galvanometer should be well insulated throughout. The battery also should be insulated as thoroughly as possible; this is a relatively easy matter when dry cells are used. The important point is to insure that all current passing through the specimen, and only that current, passes also through the galvanometer.

The galvanometer should, preferably, have a high resistance (order of 1,000 ohms) and a megohm sensibility (Par. **23** and **24**) of several hundred megohms. The temperature should always be noted, because of the large coefficient which most insulating materials have.

**138. Measuring the insulation resistance of circuits.** The insulation resistance of a "dead" circuit is conveniently made by the voltmeter method. When there is no source of e.m.f. available, various portable instruments described below are especially applicable and convenient. (Also see Sec. 21.)

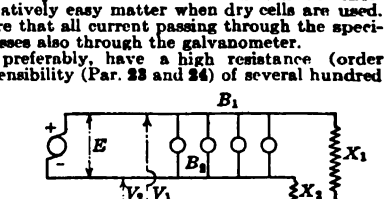

FIG. 47.—Insulation resistance of "live" circuits.

When the circuit is "alive" the following method may be used.* Fig. 47 represents diagrammatically a system with lamps and motors connected. The resistances $X_1$ and $X_2$ represent the insulation resistance from the positive and negative sides respectively to ground.

$$X_1 = \frac{R(D-d_1-d_2)}{d_2}, \text{ and } X_2 = \frac{R(D-d_1-d_2)}{d_1} \text{ (ohms)} \quad (17)$$

* Northrup, E. F. "Methods of Measuring Electrical Resistance;" McGraw-Hill Book Co. Inc., p. 210.

Digitized by Google

where $E$ = resistance of voltmeter; $D$ = deflection (scale divisions) corresponding to circuit voltage, $E$; $d_1$ = deflection corresponding to $V_1$: $d_2$ = deflection corresponding to $V_2$.

Should the system be continuous current, a D'Arsonval-type voltmeter is preferable; if it be alternating current, an electrodynamometer-type instrument should be used. This method in general will measure 1 megohm with sufficient accuracy to check specifications. If the resistance is over 1 megohm a galvanometer method is more accurate.

**139. Portable instruments for the direct measurement of insulation resistance** are classed either as testing sets or ohmmeters. **Testing sets** range from a simple Wheatstone bridge with self-contained galvanometer and battery, to elaborate cable-testing sets which include a small Wheatstone bridge, a standard 0.1 megohm resistance for insulation tests by the series galvanometer method, and a standard condenser for capacity measurements.

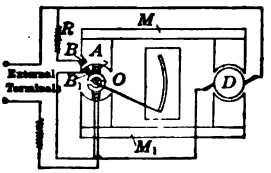

FIG. 48.—Evershed Megger.

**Ohmmeters** indicate the resistance directly. In instruments of the **Sage type**, the principle of the slide-wire bridge is employed. A scale beneath the slide wire is calibrated directly in ohms, so that when balance is obtained, the resistance is read off directly. The range can be extended by means of a number of different ratio arms, a separate scale being provided for each. Where alternating current is necessary, as in measuring electrolytes, an induction coil is introduced in the battery circuit and a telephone replaces the usual galvanometer. This type is not suitable for measuring high resistances.

**The Evershed "Megger"** is an ohmmeter which indicates the resistance by the movement of a pointer over a calibrated scale.* The principle employed is indicated in Fig. 48, where $A$ is a coil in series with the resistance to be measured and $B$, $B_1$ are coils, which, with the resistance $R$, are connected to a hand-driven generator $D$. All three coils are rigidly coupled together and are connected to the circuit by fine copper strips which exert no controlling force. When the generator is actuated a current flows through coils $B$, $B_1$ proportional to the e.m.f. generated. If the external circuit is open, $B$ and $B_1$ are deflected to the position where the least flux from the permanent magnets $M$ $M_1$ will intersect them, that is, opposite the gap in the C-shaped iron piece about which the coils $A$ and $B_1$ move. The pointer then stands at "infinity" on the scale. If now a finite resistance is connected across the terminals, the current flowing in $A$ will produce a deflecting torque toward the position shown in the figure, and, as the system moves, the coils $B$ and $B_1$ exert an opposing torque of constantly increasing magnitude. Hence the system comes to rest at a point where the two forces are balanced, the position depending upon the amount of the external resistance.

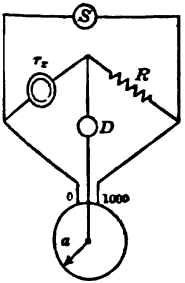

FIG. 49.—Resistance of electrolytes—Bridge method.

**140. Measurement of the resistance of electrolytes.** Electrolyte resistances are more difficult to measure than metallic resistances because of the counter e.m.f. of polarization. The several methods in use are based on the method first proposed by Kohlrausch, that is, a simple bridge arrangement in which alternating current is employed instead of direct current.

A standard Wheatstone bridge may be used, but a **slide-wire type** is found more convenient, especially if the slide wire is a long one wound spirally on a marble cylinder. When such slide-wire resistance is a separate piece of apparatus, a bridge may be easily made up and used as indicated in Fig. 49 where $R$ is a non-inductive resistance box and $r_x$

* Biddle J. G. Circular No. 740; Philadelphia, Pa., 1910.

Digitized by Google

the electrolyte. If the slide-wire scale is divided into 1,000 parts, the resistance of the electrolyte is, at balance,

$$r_x = \left\{ \frac{a}{(1000-a)} \right\} R. \qquad \text{(ohms)} \qquad (18)$$

If the source is alternating-current power of commercial frequencies an alternating-current galvanometer (reflecting electrodynamometer) may be used, the fixed coils being connected in series between the source, $S$, and the bridge and the moving coil in place of $D$ (Fig. 49). A **Vreeland oscillator** (Par. 246) is very satisfactory as a source of energy because the wave form is a pure sine curve and the frequency is sufficiently high to make the telephone sensitive.

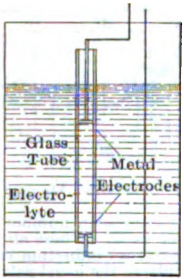

FIG. 50.—Specific resistance of electrolytes.

**141. Specific resistance of electrolytes.** Where the specific resistance or resistivity is required, a column of the liquid of known dimensions must be isolated. Fig. 50 shows a satisfactory method.* The glass tube is about 20 cm. long, 1 cm. internal diameter and open at both ends. The electrodes are of gold or platinum, the lower one being fixed in position and perforated, while the upper one is adjustable. The average cross-section must be carefully determined, preferably by volumetric measurement with mercury. The temperature is readily kept constant by stirring the liquid in the containing vessel.

**142. Internal resistance of batteries.** This measurement involves difficulties because of polarisation. One simple direct-current method is as follows. The e.m.f. of the cell or battery is first measured on open circuit. The circuit is then closed through a known resistance and the e.m.f. measured again quickly before polarization begins. The resistance is

$$R_x = \frac{R(E-E_1)}{E_1} \qquad \text{(ohms)} \qquad (19)$$

where $R$ = known resistance, $E$ and $E_1$ = voltage before and after closing circuit, respectively.

This method assumes that the internal resistance will remain constant under all conditions, which is not always the case, especially in dry cells. In a modification of this method, both readings are taken with the circuit closed, but with two slightly different values of $R$. Then

$$r_x = \frac{(E_1-E_2)R_1R_2}{E_2R_1-E_1R_2} \qquad \text{(ohms)} \qquad (20)$$

where $R_1$ and $E_1$ are the first resistance and e.m.f., respectively, and $R_2$ and $E_2$ are the corresponding values with the second resistance.

In general, such direct-current methods should be used only with primary batteries of very low resistance and with secondary or storage batteries. Alternating-current methods are more reliable.

**143. Alternating-current method of measuring internal resistance of batteries.** The Kohlrausch bridge shown in Fig. 49 can be used in this method, by inserting the cell or battery in place of the electrolyte cell. Without resistance R′ connected, the resistance of the cell will be

$$r_x = \frac{a}{(1{,}000-a)} \; R \qquad \text{(ohms)} \qquad (21)$$

If the resistance $R'$ is connected, the resistance of the cell with a current corresponding to $R'$ flowing, will be

$$r_x = \frac{aR'R}{(1{,}000-a)R-Ra} \qquad \text{(ohms)} \qquad (22)$$

**144. Effective resistance of alternating-current circuits.** The passage of alternating current through a circuit is opposed by the ohmic resistance,

* Northrup, E. F. "Methods of Measuring Electrical Resistance," McGraw-Hill Book Co. Inc., p. 241.

Digitized by Google

also by the resistance-equivalent of all the energy losses except the loss due to ohmic resistance, and by the reactance. The "ohmic resistance" is the resistance to the passage of continuous current and is therefore measured with continuous current by the methods previously described.

**145. The effective or alternating-current resistance** is that value of resistance which represents the total energy loss. It includes in addition to the ohmic resistance, the effect of any other source of lost energy, such as iron losses in a magnetic circuit, dielectric losses, and induced currents in a neighboring circuit. This effective resistance produces a potential drop which is in phase with the current. The simplest method of determining it is from the relation: $W = I^2R$, where $W$ = watts measured with a wattmeter, $I$ = current (amperes) and $R$ = alternating-current resistance (ohms).

**146. Measurement of effective resistance.** When the power is small and the power-factor is low, two-circuit electrodynamometers (Par. **33**) may be used. The exciting current must be in phase with the current through the resistance to be measured, in order to insure that the reading obtained when the moving coil is connected across the resistance is the component in phase with the current, that is, the alternating-current resistance. This condition can be established in several ways: (a) By connecting the fixed coils across a non-inductive resistance which is in series with the resistance to be measured; (b) by connecting the fixed coils to a phase shifter (Par. **213**) which is first adjusted, the moving coil being connected to a non-inductive resistance in series with the resistance to be measured, until a maximum deflection is obtained. A more sensitive method is to connect a condenser in series with the fixed coils and adjust the phase shifter for zero deflection. The dynamometer can be calibrated on a non-inductive resistance or on continuous current.

**147. Wheatstone-bridge methods of measuring effective resistance** may also be used by providing facilities for obtaining a balance for both resistance and inductance. The two "ratio" arms should be non-inductive, and the "rheostat" arm should contain both a variable resistance and a variable inductance, so that complete balance may be obtained. The detector must indicate both states of balance and should be a two-circuit electrodynamometer or a synchronously driven reversing key (Par. **39**). When using the former instrument, a resistance balance is obtained with the fixed coils excited from the same circuit, that is, in series with the bridge or across a shunt. Inductance balance is obtained with the fixed coils excited from a circuit 90 deg. from the first, the moving coils being connected across the bridge in the usual manner.

**148. The measurement of reactance and impedance** of an alternating-current circuit may be effected very simply with an ammeter, a voltmeter and a wattmeter, as indicated by the following relations, where $Z$ = impedance in ohms, $X$ = reactance in ohms, $R$ = alternating-current resistance in ohms, $W$ = power in watts, $I$ = current in amperes, $E$ = total potential-drop in volts, $\cos\theta$ = power-factor = $W/EI$.

$$(a)\ Z = \frac{E}{I},\ (b)\ Z = \frac{W}{(I^2 \cos\theta)},\ (c)\ X = \frac{W}{I^2}\tan\theta,\ (d)\ X = Z\sin\theta \qquad (23)$$

## POWER MEASUREMENTS

**149. General considerations.** When a quantity of electricity, $q$, is passed through a circuit against a difference of potential, $e$, the work done, that is, the amount of energy expended, is $qe$. Power is the rate of expending energy and at any instant is $e\partial q/\partial t = ie$, because $\partial q/\partial t = i$, where $i$ and $e$ are the instantaneous values of current and potential, respectively. Power expressed in watts is the energy expended per second, or, $W = QE/t$, where $Q$ = quantity in coulombs, $E$ = potential in volts and $t$ = time in seconds.

**150. Continuous-current power.** In a circuit supplied by a battery or a continuous-current generator, energy is expended at a uniform rate; hence, $e\partial q/\partial t = QE/t = IE$, where $Q$ = quantity in coulombs, $E$ = e.m.f. in volts, $t$ = time in seconds and $I$ = current in amperes. The power in such circuits is usually determined by measuring the current and the potential, simultaneously. Wattmeters may be used, but they are less accurate than permanent-magnet instruments, principally because of the non-uniform scale, greater temperature errors and greater sensitiveness to stray magnetic fields.

Digitized by Google

**151. Pulsating power.** Where there are instantaneous variations in the current and the potential, the power varies from instant to instant. The average power will be the average of the products of corresponding instantaneous values of current and potential and it can be measured with *strict* accuracy only with watt-meters of the dynamometer type. In rectifier circuits, the power consumption of a storage battery or a motor can be approximately measured with a voltmeter and an ammeter of the permanent magnet type. Such instruments would give a more nearly correct result than dynamometer instruments. On the other hand, the reverse will be the case with a load of incandescent lamps or heating devices. The error will depend upon the wave shape and the character of the load. The safe method is to use a dynamometer-type wattmeter.

**152. Alternating-current power.** The power in an alternating-current circuit, at any instant, is the product of the current and potential at that instant. When the load consists only of resistance, the current wave, $I$, and the potential wave, $E$, are in phase as shown in Fig. 51, and the power-factor is 100 per cent. or unity. If the products of the instantaneous values of current and potential are plotted, the curve $P$ is obtained. The average value of this curve is the power equivalent of a continuous current producing the same effect. Also, $W = EI$, where $W$ = average watts, $E$ = mean effective volts and $I$ = mean effective amperes. These values of potential and current are indicated by instruments in which the deflections are proportional to the square of the current.

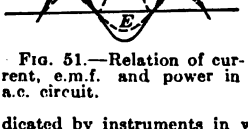

FIG. 51.—Relation of current, e.m.f. and power in a.c. circuit.

**153. When the power-factor is less than unity,** due to the fact that the circuit contains inductance or capacity (or the equivalent), the current and the potential will not be in phase. In the case of an inductive load, the current will lag behind the potential, as shown in Fig. 52. The power curve then will not be all on one side of the axis, but a part will be negative. If the current lags sufficiently, Fig. 53, the power curve will be positive half of the time and negative the other half; the average power will then be zero (or zero power-factor). This difference in phase, or time relation between the current and the potential, is called the phase angle and is usually expressed in degrees, an entire cycle being 360 deg. If the current and the

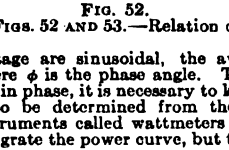

FIG. 52.

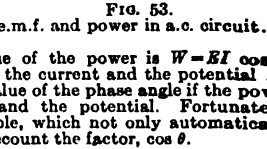

FIG. 53.

FIGS. 52 AND 53.—Relation of current, e.m.f. and power in a.c. circuit.

voltage are sinusoidal, the average value of the power is $W = EI \cos \theta$, where $\phi$ is the phase angle. Therefore if the current and the potential are not in phase, it is necessary to know the value of the phase angle if the power is to be determined from the current and the potential. Fortunately, instruments called wattmeters are available, which not only automatically integrate the power curve, but take into account the factor, $\cos \theta$.

**154. Precision measurements of power** must be made with an instrument which is equally accurate on continuous and alternating currents, in order that it may be calibrated on continuous current. Such measurements are most accurately made with **reflecting electrodynamometers** in which deflections are measured by means of a mirror, with a lamp and scale. (See Par. **33**, **64** and **97**.) The fixed coils are often divided into several sections, which may be connected in various series and parallel combinations to give large deflections over a wide range of power intensities. Instruments of this type made by the General Electric Company have current capacities from 5 amp. to 125 amp. and above, with corresponding sensibilities

Digitized by Google

of 10 and 200 watts respectively at full scale deflection, with a 50-cm. (19.7 in.) scale at 100 cm. (39.4 in.) distance.

**155. The Westinghouse "precision" wattmeter** is similar to the corresponding ammeter (Par. 99), except that the moving coils are wound with fine wire and are connected across the line instead of in series with the fixed coil. There are usually two or three current ranges, and the series resistance for the moving coil is mounted in a separate box. It therefore can be used with a wide range of voltages, from 10 volts up. Although considerable metal is used in the construction of this instrument, it is so arranged that the eddy-current error is not appreciable at commercial frequencies.

**156. The Duddell-Mather type of wattmeter** as made by Paul is a carefully constructed, semi-portable, secondary standard in which the current element comprises four fixed coils connected in series, and the potential or moving element consists of four coils connected in series, all astatically arranged. The moving element is suspended by a silk fibre and a spiral spring furnishes the controlling force. It is a torsion-head instrument like the Westinghouse wattmeter.

**157. Commercial indicating wattmeters** are made in two general forms, the electrodynamometer type and the induction type.

**158. The Weston model-16 and the General Electric type P₂ instruments** are well-known examples of the **electrodynamometer class.** Fig. 54 shows the general arrangement. The current or series element consists of two fixed coils wound with heavy wire or strip, which are connected in series with each other and with the main circuit. The potential or shunt element is a moving coil mounted on a shaft supported between jewel bearings and placed between the two fixed coils. This coil consists of a large number of turns of fine wire, as in voltmeters; it is connected in series with a relatively large amount of non-inductive resistance, across the main circuit. The controlling force comprises one or more spiral springs.

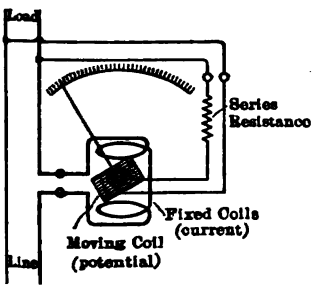

FIG. 54.—Diagram, electrodynamometer type wattmeter.

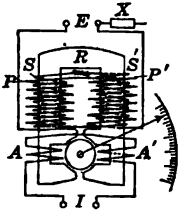

FIG. 55.—Diagram, Westinghouse induction type wattmeter.

**159. The inclined-coil type of wattmeter** (General Electric Company) is similar in principle (Par. 158), but the centre lines of the fixed coils and the moving coil make an angle of about 45 deg. with each other, instead of 90 deg., the object being to make the scale more open, or more uniformly graduated.

**160. The Westinghouse portable wattmeter** is the most important example of **induction-type** wattmeters. The principle is exactly the same as that of the induction watthour meter (Par. 202); but instead of allowing the moving element to rotate, the torque is opposed by a spiral spring and hence the deflection is proportional to the power. Fig. 55 shows the schematic arrangement, where $AA'$ are the current or series coils, $PP'$ the potential or shunt coils and $SS'$ the compensation coils by means of which, together with the adjustable resistance, $R$, the exact quadrature relation is obtained as in watt-hour meters. This type is also made in polyphase form by having two sets of current and potential elements acting on a common

Digitized by Google

moving disc, or drum, as in the polyphase watt-hour meter. It is obvious that instruments of this type are limited to the frequency for which they are designed.

**161. The Whitney wattmeter** operates on the dynamometer principle (Par. 158) except that it is a torsion-head instrument, the moving element being kept in a fixed position by twisting the torsion head to which the control spring is attached. The pointer attached to this head moves over the scale. This method permits using a very long scale, extending around a full circle.

**162. Wattmeters for switchboard use** employ both the electrodynamic and the induction principles. Weston instruments are similar to the portable electrodynamometer instrument (Par. 158). The General Electric edgewise type "H" instruments are dynamometer types while type I is of the induction type. Westinghouse switchboard instruments are also induction type.

**163. The calibration of wattmeters of the dynamometer type** should be done with continuous current. It is customary to make such tests at a fixed potential, usually 100 or 200 volts and to vary the current to give the required watts. The potential is held constant at the desired value by means of one standard (standard voltmeter or potentiometer) and the current is read on another standard (standard ammeter, or potentiometer with standard resistance). It is more convenient to obtain the potential and the current from separate sources, because the process of adjustment of one circuit will not affect the other. In the case of instruments of large capacity this method economizes energy, because only three or four volts are necessary for the current circuit.

**164. Calibration of induction-type wattmeters.** These instruments must be checked on alternating current of the frequency for which they are designed. This check is made by comparison with a secondary standard, which in turn is checked on continuous current. Polyphase instruments may be checked as single-phase instruments by connecting the current circuits in series and the potential circuits in parallel. In the case of induction-type instruments stray magnetic flux from one element may affect the other, in which case the calibration should be made on a polyphase circuit.

**165. The inductance error in wattmeters** may, under certain conditions, become very important. While the theory of the electrodynamometer type of wattmeter assumes that the potential circuit is non-inductive, this is not strictly true in the actual instrument because of the inherent inductance of the moving coil. Ordinarily, however, the non-inductive series resistance is sufficiently large to make the effect of this inductance negligible at ordinary frequencies and power-factors. But with low power-factors, the lag angle in the potential circuit may have to be considered. The power in an alternating-current circuit is $W = EI \cos \theta$, where $W$ = power, $I$ = current, $E$ = e.m.f. and $\cos \theta$ = power-factor of circuit. When the power-factor is unity, $I$ and $E$ are in phase, but the potential-circuit current lags slightly behind $E$, thus producing the effect of a small power-factor. If, for example, the lag-angle, $\theta$, is 2 deg., $\cos \theta = 0.9994$ and the error is ordinarily negligible. If the power-factor is 50 per cent., the lag angle in the wattmeter is $(60 - 2) = 58$ deg. The cosine of 60 deg. is 0.50 while the cosine of 58 deg. is 0.53, thus introducing an error of 6 per cent.

**166. The stray-field error** in unshielded, non-astatic, electrodynamometer wattmeters may be anything from zero to 25 per cent. with an alternating magnetic field of 5 lines per square centimeter, and from zero to 75 per cent. at 10 lines, depending upon the direction of the field and the coil deflection. A shield, properly made and placed, is extremely efficient, reducing the effect of a field of 20 lines per square centimeter to practically zero, without introducing eddy current or other errors.

**Wattmeters of the Kelvin balance type**, in which the coils are astatically arranged, are practically immune from these troubles except in an intense field which is not uniform throughout the space occupied by the moving system; such a condition may arise, for example, when the wattmeter is close to a conductor carrying a very large current. Induction-type instruments employ much stronger field strengths and are not appreciably affected except by very strong fields

Digitized by Google

**167. Wattmeter connections to line.** Care should be taken so to connect a wattmeter into the main circuit that the moving-coil end of the potential circuit and the current coil are on the same side of the circuit being measured. Otherwise there may be sufficient electrostatic attraction between the two windings to produce an error; or, if the potential is sufficiently high, the insulation between the windings may be broken down. The latter may be guarded against by connecting the binding post at the moving-coil end of the potential circuit to the proper current post with fine fuse wire.

**168. Correction for wattmeter losses or energy consumption.** Where small quantities of power are being measured, the losses in the circuits of the instrument itself should be taken into account. It will be noted in Fig. 56 that the instrument is measuring its own current circuit loss, or series $I^2R$ loss. If the instrument loss cannot be neglected, it is better to

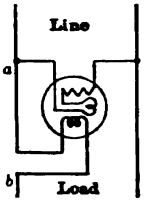

FIG. 56.—Power measurements in single-phase circuits with wattmeter.

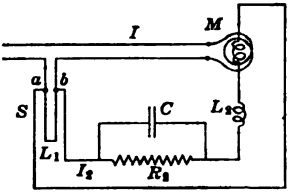

FIG. 57.—Electrodynamometer arrangement for measuring small amounts of power.

connect the potential circuit to the load side (*b* instead of *a*) and include the potential circuit loss in the measurement instead of the current circuit loss, because the former not only remains constant but is more easily calculated. Wattmeters are often arranged to correct or compensate automatically for this loss by means of a few turns on the fixed coil, connected in series with the potential circuit and in opposition to the fixed coil. This arrangement cannot be used with shunt-type instrument transformers nor when checking the wattmeter with separate sources of e.m.f. and current. A separate connection is usually provided, however, for this purpose. In general it is safer always to use this "independent" connection, making allowance for the potential loss, when necessary, by calculation.

**169. Measurement of very small amounts of power.** Where the power is extremely small, only a few watts, reflecting electrodynamometers are most accurate. This is especially true when the power-factor is low, the

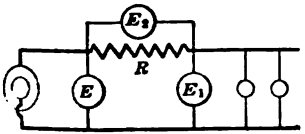

FIG. 58.—Power in single-phase circuit, three-voltmeter method.

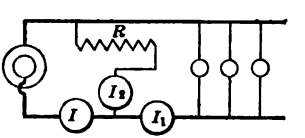

FIG. 59.—Power in single-phase circuit, three-ammeter method.

potential high and the current low, or *vice versa*, as for example the losses in alternating-current conductors, in dielectrics, instrument circuits and magnetic circuits. The fixed coils may be connected directly in series with the main circuit or to a non-inductive shunt in the circuit. At low potentials, the series resistance in the moving-coil circuit may not be sufficient to eliminate the effect of inductance but this can be accomplished by shunting the resistance with a condenser as shown in Fig. 57. When the potential circuit is short-circuited at *a*, *b*, the capacity *C* or resistance $R_2$ is adjusted until there is no deflection with full current in the fixed coil. Calibration is of course made with continuous current.

**170. Measurement of power in a single-phase circuit.** One wattmeter connected as shown in Fig. 56 will read true watts. The power may also be measured without the use of a wattmeter, by three voltmeters or three ammeters.

In the "**three-voltmeter**" method, a known non-inductive resistance, $R$, is connected in series with the load as shown in Fig. 58, where $E$, $E_1$ and $E_2$ are points where voltmeter readings are to be taken. The power in watts is

$$W = \frac{E^2 - E_1^2 - E_2^2}{2R} \quad \text{(watts)} \qquad (24)$$

Similarly, in the "**three-ammeter**" method, Fig. 59, the power in watts is

$$W = R\left(\frac{I^2 - I_1^2 - I_2^2}{2}\right) \quad \text{(watts)} \qquad (25)$$

**171. Two-phase, four-wire circuit.** Two wattmeters, connected as shown in Fig. 60, are sufficient, these conditions being equivalent to two single-phase circuits. The total power is obviously the arithmetical sum of the readings of the two instruments.

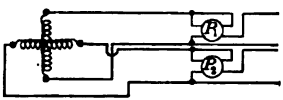

FIG. 60.—Power in two-phase, four-wire circuit.

**172. Two-phase, three-wire circuit.**—Two wattmeters should be connected as shown in Fig. 61, the total power being the *algebraic* sum of the two readings. This connection is correct for all conditions of load, balance and power-factor. One wattmeter may be used as in Fig. 62, provided there is no load across the outer conductors and the phases are *balanced* as to load and power-factor.

**173. Two-phase, four-wire, interconnected circuit.** Three wattmeters can be used, connected as in Fig. 63, the total power being the *algebraic* sum of the three readings. This connection is correct under all conditions of load, balance and power-factor. Two wattmeters, one in each phase, will give the true power only when the load is balanced.

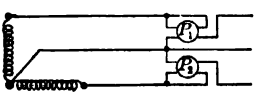

FIG. 61.—Power in two-phase, three-wire circuit.

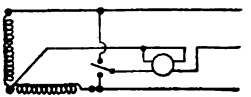

FIG. 62.—Power in two-phase, three-wire circuit.

**174. Three-phase, three-wire circuits.** Two wattmeters may be used, connected as in Fig. 64, the total power being the *algebraic* sum of the two readings. At unity power-factor, each instrument will indicate half the total power and at 50 per cent. power-factor one instrument will indicate the total power, the other instrument reading zero. At less than 50 per cent. power-factor, one instrument will read negative. (See Par. **209** for method of verifying power-factor.)

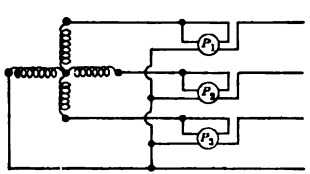

FIG. 63.—Power in two-phase, four-wire interconnected circuit.

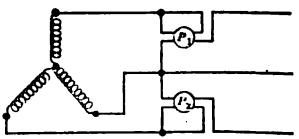

FIG. 64.—Power in three-phase, three-wire circuit, two wattmeters.

Digitized by Google

**175. Three-phase, three-wire circuits, balanced load.** When the load is *balanced* the power may be measured with one wattmeter by the following methods.

(a) With **"star" box** or artificial neutral as shown in Fig. 65. The total power is three times the reading of the wattmeter. The resistance in each leg of the star box should be non-inductive and small compared with that of the potential circuit of the wattmeter, so that the current taken by the latter will not disturb the potential at the neutral point.

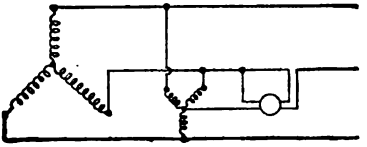

FIG. 65.—Power in three-phase, three-wire circuit, one-wattmeter, with "star" box.

(b) With **"Y" box** as shown in Fig. 66. The total power is three times the wattmeter reading. The arrangement is similar to (a), one leg of the star box being replaced with the potential circuit of the wattmeter itself. The other two legs have the same impedance as the potential circuit of the wattmeter.

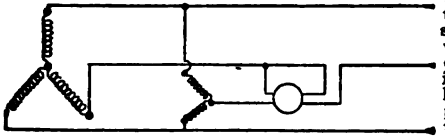

FIG. 66.—Power in three-phase, three-wire circuit, one wattmeter, with "Y" box.

(c) With a **"T" reactance coil** as shown in Fig. 67. The total power is twice the wattmeter reading. The impedance of the reactance coil must be small compared with that of the potential circuit of the wattmeter, so that the current taken by the potential circuit will not disturb the potential at *O*.

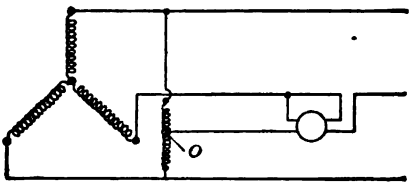

FIG. 67.—Power in three-phase, three-wire circuit, one wattmeter, with "T" reactance coil.

**176. Three-phase, four-wire circuits.** Three wattmeters are used as shown in Fig. 68. The total power is the *algebraic* sum of the three readings. This method is correct under all conditions of load, balance, and power-factor. A three-phase, "star" system with a grounded neutral is virtually a four-wire system and the power should be measured with three wattmeters. Obviously, if the load is balanced, one wattmeter can be used, the total power being the indication of the wattmeter multiplied by three. The current coil should be connected in series with one conductor or phase wire and the potential coil between that conductor and the neutral.

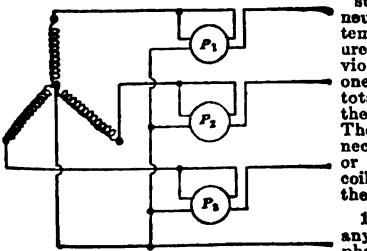

FIG. 68.—Power in three-phase, four-wire circuit.

**177. "N"-phase circuit.** In any system whatsoever, of "n" phases, the true power may be measured by connecting a wattmeter in each phase, the current coil being in series with the line and the potential coil connected between that line and any common

Digitized by Google

point $P$ of the system, which may or may not be the neutral. The total power is the algebraic sum of the readings of all of the wattmeters so connected.*

**178. Power measurements on high-voltage circuits** should preferably be made with series-type and shunt-type instrument transformers. If the instrument wattmeter is connected directly to the circuit with series resistance in the potential circuit, the circuit should be grounded at the instrument in order to avoid errors of electrostatic attraction, and also possible injury to the instrument or the observer. The current-capacity limit of commercial wattmeters is about 200 amp. beyond which series transformers with 5-amp. instruments are used, irrespective of potential.

**179. Corrections where instrument transformers are used in accurate power measurements.** In every case the **true ratio** and **phase angle** should be known (Par. **79** and Par. **104, 105**). The general effect of the phase changes in the instrument transformers is to make the angle between the current and the potential in the wattmeter larger or smaller than that between the current and the e.m.f. of the circuit being measured.

If $\cos\theta$ = true power-factor and $\cos\theta_2$ = apparent power-factor (i.e., power-factor in the wattmeter obtained from the ratio of the watts and volt-amperes in the wattmeter), true watts = $(\cos\theta/\cos\theta_2) \times$ wattmeter reading. The apparent power-factor, $\cos\theta_2 = \cos(\theta \pm \alpha \pm \beta \pm \gamma)$, where

$\theta$ = phase angle in main circuit,
$\alpha$ = equivalent phase angle in wattmeter,
$\beta$ = equivalent phase angle in current transformers,
$\gamma$ = equivalent phase angle in voltage transformers.

The angles $\alpha$, $\beta$ and $\gamma$ are given positive (+) signs when they tend to decrease and negative (−) signs when they tend to increase the phase angle between the current and voltage in the instrument.†

**180. Power-factor.** The power-factor of a circuit is the ratio of the true power in watts, as measured with a wattmeter, to the apparent power obtained from the product of the current and the potential, in amperes and volts respectively. In the ordinary continuous-current circuits, the power-factor is obviously unity but in rectifier circuits, for example, it may be slightly less than unity. In alternating-current circuits, the power-factor is usually less than unity because the current and the potential are not in phase. When the wave form is sinusoidal, the power-factor is equal to the cosine of the angle of lag.

**181. The power-factor of single-phase circuits** is obtained from wattmeter, voltmeter and ammeter readings, by the relation $W/EI = \cos\theta$ where $W$ = watts, $E$ = volts and $I$ = amperes.

**182. The power-factor of polyphase circuits** which are balanced is the same as that of the individual phases. When the phases are not balanced, the true power-factor is indeterminate. For all practical purposes, however, it is sufficiently correct to assume the power-factor to be that obtained by methods which give the average of the power-factors of the separate phases. In the **wattmeter-voltmeter-ammeter method**, the power-factor is, for a two-phase, three-wire circuit $W/\sqrt{2}$ $(EI)$, (I in middle wire, E between outer wires) and for a three-phase, three-wire circuit the power-factor is $W/\sqrt{3}$ $(EI)$, wherein $W$ = watts, $E$ = volts and $I$ = amperes. In the **two-wattmeter** method, the power-factor of a two-phase, three-wire circuit is obtained from the relation $W_2/W_1 = \tan\theta$, where $W_1$ is the reading of a wattmeter connected in one phase in the same manner as a single-phase circuit, and $W_2$ is the reading of a wattmeter connected with its current coil in the first phase, in series with the first wattmeter, and the potential coil across the second phase. Obviously, if the load is steady, one wattmeter is sufficient. If the phases are not balanced, the readings should be repeated with the instruments in the second phase, the true power-factor being taken as the average of the two results. In a **three-phase, three-wire circuit**, the power-factor can be calculated from the readings of two

wattmeters connected in the standard method for measuring power, as follows: $\{(W_1 - W_2)/(W_1 + W_2)\}\sqrt{3} = \tan\theta$, where $W_1$ is the larger reading, which is always positive, and $W_2$ is the smaller reading which may be either positive or negative.

**183. Power-factor meters** are instruments which indicate directly the power-factor of the circuit. Commercially there are two general classes, those involving the principle of electrodynamometer **wattmeters** and those based on the principle of induction wattmeters. The essential features of a Weston single-phase power-factor meter of the first class are shown in Fig. 69. It will be noted that the arrangement is similar to that in wattmeters, except that there are two coils, $M$, $M^1$, in the moving system instead of one. One coil, $M$, is connected across the line and in series with a resistance $R$, while the other coil, $M^1$, is connected in series with an inductance $L$. The current in the coil, $M^1$, will therefore be about 90 deg. out of phase with that in coil $M$. When the power-factor is unity, the reaction between the fixed coils, $F$, $F^1$, and the moving coil $M$ will be a maximum while that between $FF^1$ and $M^1$ will be a minimum. The torque exerted on $M$ will cause the moving system to take the position of minimum torque, that is, where the plane of $M$ will be parallel to that of $FF^1$; the corresponding mark on the scale will therefore be 100. Similarly, at zero power-factor, coil $M^1$ will exert all of the torque and cause the moving system to take a position where the plane of $M^1$ will be parallel to that of $FF^1$; the corresponding indication is therefore zero. Theoretically, the indications will be **affected by the frequency**, because the current in $L$ depends upon the frequency, but by proper design of the reactor, $L$, the effect of moderate variations in frequency can be eliminated.

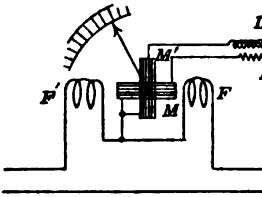

FIG. 69.—Diagram, Weston single-phase power-factor meter.

In the **polyphase meter**, Fig. 70, the inductance $L$ is not required and the instrument is therefore entirely independent of the frequency. There are three coils in the moving system, one connected across each phase. The principle of operation is exactly the same as in the single-phase instrument, the moving system taking up a position where the resultant of the three torques will be a minimum, which position will vary with the average power-factor of the circuit.

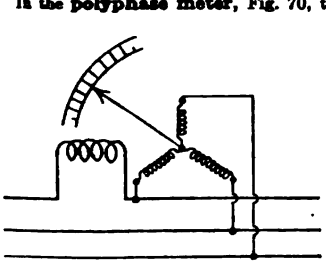

FIG. 70.—Diagram, Weston polyphase power-factor meter.

**184. In Westinghouse power-factor meters**, the dynamometer principle described in Par. 182 is used in some types. In others the induction principle is employed in the same manner that is applied in synchroscopes (Par. 289–291).

**185. General Electric power-factor meters** employ the electrodynamometer principle (Par. 182) in polyphase instruments. No single-phase instruments are made by this company.

## ENERGY MEASUREMENTS

**186. The practical unit of electrical energy** is the **watt-hour**, which is the energy expended in 1 hr. when the power or rate of expenditure is 1 watt.

**187. Energy is usually measured in watt-hours**, with **watt-hour meters** (often incorrectly called integrating or recording meters). All watt-hour meters are, in reality, small motors in which the speed is propor-

Digitized by Google

tional to the power and the revolving element operates a registering mech anism on which the energy consumption is recorded. Meters for con tinuous current are usually of the type which utilize the electrodynami principle of direct-current motors, while those for alternating curren utilize the principle of induction motors.

**188. Continuous-current watt-hour meters.** Continuous-current meters may be divided into two classes, the **commutator type** and th **mercury motor type.**

**189. Commutator-type meters** are similar in principle to shunt motors The essential features are shown in Fig. 71. The moving element consist of an armature, *a*, a commutator, *c*, and a light metal disc, *d*, all mounted on a steel shaft which rotates in a jewel bearing. The armature is connected to the external circuit by means of very light silver-tipped brushes. In series with the armature is a light-load com pensation coil, *s*, and a resistance, *r*. The field coils are indicated at *f*, *f*.

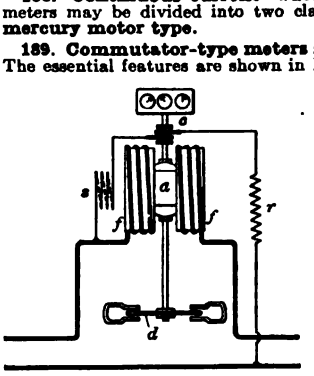

FIG. 71.—Diagram, commutator-type watt-hour meter.

**190. Characteristics of commu tator-type meters.** The essentia differences between this type of watt hour meter and a two-pole shunt moto are as follows: (a) entire absence o iron in the magnetic circuits; (b) th armature element is connected across the circuit and carries a very smal current, while the field element is in series with the circuit and carries th main current; (c) the speed increases as the field strength increases which i opposite to the effect in a shunt motor

**191. The principle of operation of commutator-type meters** i as follows. The torque is proportional to the current in the armature coil and to the field strength. Since there is no iron in the magnetic circuit, th latter is always proportional to the field current, hence the torque is pro portional to the two currents (as in a dynamometer wattmeter). The cur rent in the armature being proportional to the line potential, and the fiel current equal or proportional to the line current, the torque is proportiona to the power. In order to make the speed proportional to the power, mechanical load must be provided, in which the counter-torque will be pro portional to the speed. This load usually takes the form of a circular disc *d* (Fig. 71) of thin copper or aluminum which revolves between the pole of one or more permanent horseshoe magnets, with poles very close together The eddy currents induced in the disc react with the permanent-magne field, producing a counter-torque which will always be proportional to th speed. As the load current increases, the torque of the motor element in creases and the speed increases, because there is practically no counte e.m.f. in the armature, *s*. But as the speed increases, the counter-torqu of the disc or generator element also increases and a speed is finally reache where the two torques balance each other and the speed remains constant Thus, theoretically, the speed will always be proportional to the power in th circuit. Each revolution represents a definite amount of energy, and b connecting the shaft to a suitable recording mechanism similar to that o gas and water meters, the total energy consumed is automatically registered.

**192. Effects of friction and temperature in commutator-typ meters.** In practice, certain conditions prevent the speed from bein always proportional to the load, the principal factors being friction an temperature. **Bearing friction** is reduced to a minimum by using polishe sapphire or diamond jewels, with either a polished cone-shape shaft—en or a steel ball. Thus the contact surface is reduced practically to a point The weight is reduced by using hollow shafts and very light aluminum o non-metallic frames for the armature windings. **Commutator friction** is reduced to a minimum by making the commutator diameter small, an

Digitized by Google

using round brushes so that contact is made practically at a point. The gears in the registering mechanism are made as light as possible. The effect of friction is smaller as the torque is increased; hence the **ratio of torque to weight** is made as large as possible by making the armature spherical, which gives the maximum torque for the minimum amount of wire (weight).

**193. Compensation for friction in commutator-type meters.** Friction cannot be entirely eliminated and its effect is marked at light load, necessitating the use of a **compensating device.** This usually consists of a few turns of fine wire on the field coil, which are connected in series with the potential circuit. These turns are wound in a separate coil and the amount of compensation can be adjusted for each meter individually either by altering the position of the coil with respect to the field coils, as in General Electric and Westinghouse meters, or by changing the number of turns as in Columbia and Duncan meters.

**194. Compensation for temperature in commutator-type meters.** Temperature affects the performance of meters by: (a) changing the resistance of potential circuit; (b) changing the resistance of the drag disc; and (c) changing the strength of the permanent magnets. These changes produce a combined or resultant effect, which is compensated for by using for the series resistance in the potential circuit, one or more materials so combined that the final temperature coefficient of resistance counteracts the other effects when the air temperature changes.

**195. The mercury-motor-type** meter is most prominently represented by the direct-current meter made by the Sangamo Electric and Manufacturing Co. Fig. 72 shows diagrammatically the circuits and scheme of operation. *D* is a solid copper disc floating in mercury, *F* a float which supports the shaft and eliminates a jewel bearing; *H* is a laminated iron core and *C* is a chamber filled with mercury. The flux produced in the core, *H*, by the shunt coil, traverses the disc at two points which are diametrically opposite. The line current passes from *L* to $L_1$ through the mercury and diametrically through the disc. This disc being cut by flux, a torque is produced which is proportional to the current and the e.m.f.

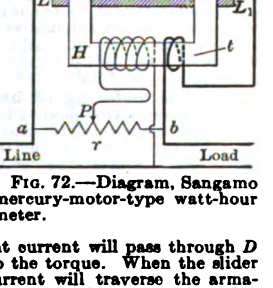

FIG. 72.—Diagram, Sangamo mercury-motor-type watt-hour meter.

**196. Compensation for friction in mercury-motor-type meter.** The friction due to the disc rotating in the mercury is **compensated in two ways.** One method is shown in Fig. 72. A high resistance, *r*, is connected in shunt with the armature, *D*, and the e.m.f. circuit is completed by the sliding contact, *P*. When the slider is at *b*, practically all of the shunt current will pass through *D* because of the resistance, *r*, thus adding to the torque. When the slider is at *a*, practically none of the e.m.f.-coil current will traverse the armature. In the second method, a circuit consisting of two wires of dissimilar metals, which form a thermocouple, is connected in parallel with the mercury chamber terminals, *L*, $L_1$. This couple is surrounded with a heating coil connected in series with the potential circuit. The e.m.f. produced by the couple causes current to flow through the disc thus producing the necessary torque to overcome the effect of friction at light load. The **increased mercury friction at high speed** is compensated by a series turn (or half a turn), *t*, on the core H. The drag or counter-torque is obtained with a separate disc and permanent magnets (not shown) in the usual manner.

**197. Speed adjustments.** The speed at all loads is equally affected by shifting the drag magnets diametrically with respect to the meter shaft, thus altering the retarding torque. This torque is a minimum with the magnets close to the shaft and a maximum with magnets near the edge of the disc. The speed at light load is adjusted independently as indicated in Par. 198.

**199. Three-wire circuits are metered with two, two-wire meters** of the kind described (Par. **188** to Par. **198**), **or a three-wire meter.** The latter which is usually made in the **commutator type**, is the same as the two-wire meter except that the two field coils (which should be alike) are separated electrically, and one is connected in each outer wire in such a manner that their fields are cumulative as before. When the load is exactly balanced, the conditions are obviously the same as in a two-wire meter, and when unbalanced the two field strengths add together so that the speed is proportional to the total current.†

**200. The metering of heavy-current circuits** by means of standard meters becomes troublesome because of the large conductors required in the fields. While such meters have been made in capacities up to 20,000 amp., they are very costly and not satisfactory at light loads. Watthour meters have been developed by some manufacturers, along standard lines, for operation with shunts. In order to develop sufficient torque without an excessive shunt loss, it is necessary to employ shunts having small drop, large field coils on the meters and relatively large leads from meter to shunt. Where the meter has to be some distance from the shunt, the leads may have to be nearly as large as the wires in the main circuit, in order to keep down the resistance.

Another way to avoid the use of large meters is to connect several smaller meters in parallel. Care should be taken to make the resistance of the several branches equal, if the meters are of the same capacity; or, if the meters are of different capacities, inversely proportional to the capacities of the meters. This will insure that none of the meters are overloaded.

**201. Alternating-current watt-hour meters.** Alternating-current energy is almost always measured with induction type meters. Commutator meters are seldom used on alternating-current circuits for the very practical reason that induction meters are not only **more accurate,** but much **less expensive** in first cost and in maintenance.

Digitized by Google

**202. Induction-type watt-hour meters** operate on the principle of the rotating magnetic field of the induction motor. The essential features of the principal makes of watt-hour meters are shown in the diagrammatic sketch, Fig. 73. $P$ is the potential coil; $S$ the series coil, and $C$ a compensating coil. A metallic disc is free to revolve between the poles. The alternating magnetic fluxes from these poles will establish currents in the disc about as indicated by the arrows in the sketch at the right, which shows a portion of the disc and the poles. The potential winding, $P$, has many turns and is therefore highly inductive, while the series winding, $S$, is practically non-inductive; thus the fluxes produced by these two circuits are practically 90 time-degrees apart. Each flux is in phase with the current which produces it; and the e.m.f. generated in the disc, which is cut by the flux, is in time quadrature with the generating flux. Therefore, if it is assumed that the fluxes due to $P$ and $S$, respectively, are in quadrature, the eddy currents produced by $P$ will be a maximum at the same instant that the flux from $S$ is a maximum, and *vice versa*. Thus a torque will be produced which is proportional to the instantaneous product of the eddy currents in the disc and the flux from the pole under which the current is flowing. This torque is proportional to the power used in the load circuit providing the time-phase difference of the currents in coils $P$ and $S$ is exactly 90 deg. at unity power-factor. The necessary retarding action or counter-torque is obtained with permanent magnets on this same disc as described under direct-current meters (Par. **191**).

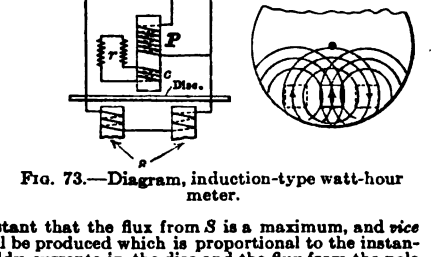

FIG. 73.—Diagram, induction-type watt-hour meter.

**203. Compensating coil on induction-type meters.** If the phase quadrature is not exact (Par. **202**), the meter will obviously not register correctly under any condition. In consequence of the ohmic resistance of the potential circuit, the current is never exactly 90 deg. behind the impressed e.m.f. At any instant, the flux $E_f$ (Fig. 74) from the potential pole, instead of being in phase with the eddy currents, $I_e$, due to the line current, is slightly behind, as indicated. The torque is therefore proportional to the product $I_e$ and $oa$, instead of $I_e$ and $E_{ff}$. The meter will therefore run slow, but as a practical matter the error is so small that at unity power-factor it is insignificant. The error rapidly becomes large, however, as the power-factor decreases. As practically all alternating-current circuits have a power-factor less than unity, a **compensating coil** is used to eliminate the error. This coil is a short-circuited coil placed on the potential pole (see Fig. 73) and in which a current is induced 90 deg. behind the generating (potential) flux. Its flux, $S_f$, will be in phase with that (induced) current and therefore 90 deg. from $E_f$, with which it will combine. By adjusting the value of the resistance (lag adjustment) $r$ (Fig. 73) the resultant flux can be brought into exact phase with $I_e$ and the meter will then register correctly on all power-factors. It is evident that with lagging power-factor in the circuit, a meter will be slow if "under-lagged" and fast if "over-lagged." The opposite results will occur with a leading power-factor.

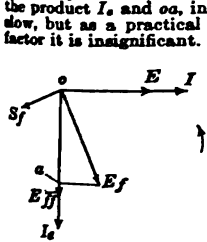

FIG. 74.—Theory of lag adjustment, induction watt-hour meter.

**204. Friction compensation.** The friction in an induction-type meter is much less than in a commutator-type meter because of the absence of a commutator and an armature. On the other hand, the torque is less (compare tables of characteristic data, Par. **198** and Par. **206**) and the effect of friction at light load has to be compensated. The principle employed in

Digitized by Google

practically all meters is that in which a flux is produced at the potential pole face, slightly out of phase with the main flux. Thus eddy currents will be produced in the disc which will be in phase with a small component of the main flux, giving rise to a slight torque which can be made sufficient to overcome the friction torque. This "out-of-phase" flux is produced in various ways in different meters. A common method is to place a short-circuited copper circuit or thin copper punching ("shading strip") in the potential-pole air-gap, in an unsymmetrical position, so that the desired unbalanced flux will be obtained. In the Columbia meter, the effect is accomplished by unbalancing the flux of the two potential poles by means of magnetic shunts.

**205. Adjustments of induction-type meters.** Facilities are usually provided for conveniently adjusting the meter accuracy at light and full load. The position of the light-load compensation coil can be changed with conveniently located screws, and the light-load speed thus altered. Speed adjustment at all loads is obtained by shifting the drag magnets with respect to the axis, as in direct-current meters, or by shunting the flux by means of a movable soft-iron **keeper** bridging the air gap. The power-factor or lag adjustment is made at the factory and if properly done should never require readjustment.

**207. Measurement of energy in alternating-current circuits.** The energy consumption in alternating-current circuits is measured with watt-hour meters connected in exactly the same manner as are wattmeters for the measurement of power. (See Figs. 60 to 68.) In **three-wire, two-phase** or **three-phase systems, polyphase meters** may be used. Such meters comprise merely two single-phase meters in one case, with a common shaft, and connected to the main circuit in the same manner as two single-phase meters.

**Four-wire systems,** unless balanced, require **three single-phase meters.** A **three-phase system** with a **grounded neutral** should be considered a four-wire system requiring three meters, unless it is completely balanced.

**208. The total energy in a three-phase circuit** is the algebraic sum of the indications of two single-phase meters, just as the total power is the algebraic sum of the readings of two wattmeters (Par. **174**). If a **polyphase meter** is used, the summation is automatically performed, and

* From "Electrical Meterman's Handbook," N. E. L. A., 1912, to which the reader is referred for further data.

Digitized by Google

when one element tends to run backward (power-factor less than 50 per cent.), it simply reduces the torque of the other one, so that the actual speed is still proportional to the net power in the circuit.

**209. Polyphase meter connections.** Obviously it is extremely important that the various circuits of a polyphase meter are properly connected. If, for example, the current-coil connections are interchanged and the line power-factor is 50 per cent., the meter will run at the normal 100 per cent. power-factor speed, thus giving an error of 100 per cent.

A **test for correct connections** is as follows: If the line power-factor is over 50 per cent., rotation will always be forward when the potential or the current circuit of either element is disconnected, but in one case the speed will be less than in the other. If the power-factor is less than 50 per cent. the rotation in one case will be backward.

When it is not known whether the power-factor is less or greater than 50 per cent., this may be determined by disconnecting one element and noting the speed. Then change the potential connection from the middle wire to the other outside wire and again note the speed. If the power-factor is over 50 per cent., the speed will be different in the two cases, but in the same direction. If the power-factor is less than 50 per cent., the rotation will be in opposite directions in the two cases.

**210. Use of instrument transformers with watt-hour meters.** When the capacity of the circuit is over 200 amp. series-type instrument transformers are generally used to step-down the current to 5 amp. If the potential is over 440 volts, series transformers are almost invariably used, irrespective of the magnitude of current, in order to insulate the meter from the line; in such cases, shunt-type transformers are also used to reduce the voltage to 110 volts. The **ratio and phase-angle errors** of these transformers (Par. **79** and Par. **104**) should be taken into account where high accuracy is important, as in the case of a large installation. These errors can be largely compensated for by adjusting the meter speed. The per cent. error corresponding to various phase angles is given in Par. **179**.

**211. The accuracy of a watt-hour meter** is the percentage of the total energy passed through a meter which is registered by the dials. The watt-hours indicated by the meter in a given time are noted, while the actual watts are simultaneously measured with standard instruments. On account of the time required to get an accurate reading from the register, it is customary to count revolutions of the rotating element instead of the register. The accuracy of the gear ratio between the rotating element and the first dial of the register can be determined by count. Since the energy represented by one revolution, or the **watt-hour constant**, has been assigned by the manufacturer and marked on the meter, the indicated watt-hours will be $K_h \times R$, where $K_h$ = watt-hour constant and $R$ = the number of revolutions. (See Testing Formulæ, Par. **223**.)

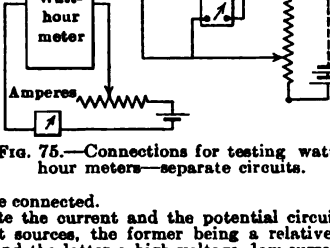

FIG. 75.—Connections for testing watt-hour meters—separate circuits.

**212. Laboratory tests.** Obviously the source of energy for meter testing should be as steady as possible. Storage batteries are largely used for direct-current meters; and special alternators, whose speed can be controlled, are used for alternating-current meters. The testing load may be banks of lamps, to which the meter and standard instruments are connected.

**A better method** is to separate the current and the potential circuits and connect them to independent sources, the former being a relatively large-current, low-voltage source and the latter a high-voltage, low-current source. Conditions are more easily adjusted by this method and in large meters a saving of energy is effected.

Where separate sources are used for the current and the potential coils, carbon rheostats are convenient for adjusting the current, and high-resistance rheostats connected "potentiometer" style are convenient for controlling

Digitized by Google

the voltage, as indicated in Fig. 75. Resistance in the potential circuit of alternating-current meters will alter the quadrature phase relation, and therefore voltage regulation should be obtained with a variable ratio auto-transformer, an induction regulator or by field control.

**213. Power-factor variation, in meter testing,** can be obtained by several methods. In the **two-alternator** method, two generators are mounted on a common base, with a common shaft. The stationary members (armature or field) are made movable about the shaft with respect to the base and to each other. Thus with the potential coil of the meter connected to one machine, and the current coil to the other, any phase relation can be obtained by adjusting one movable member with respect to the other.

In the **transformer** method, a transformer with a large number of steps, or a variable-ratio auto-transformer, is connected across one phase of a polyphase circuit and the potential coil of the meter is connected in such a manner that any phase relation can be obtained. Thus, referring to Fig. 76, the current coil of the meter is connected in series with conductor *a* of a three-phase circuit, and the potential coil is connected to *o* and to *c*, the latter being a tap on a transformer connected across phase *bc*. It is apparent that **any phase angle** between the current and the potential can be obtained in a range from 0 deg. to 60 deg. by moving the connection point *c* along the transformer winding. Angles from 60 deg. to 90 deg., lead or lag, can be obtained by changing the transformer to either of the other two phases and the meter connection from *o* to *x* or *y*. These changes can be instantly made with suitable switching arrangements. A similar arrangement can be made for a two-phase circuit, Fig. 77. It is also convenient to introduce such a transformer between the taps *o*, *c* and the meter, for the purpose of compensating for the variations in the voltage between *o* and *c*, and keeping the voltage constant at the meter. Two variable-ratio auto-transformers arranged in this manner make a convenient **phase shifter**.

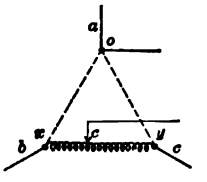

FIG. 76.—Power-factor variation—transformer method.

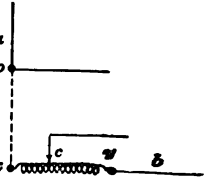

FIG. 77.—Power-factor variation—transformer method.

In the **reactance-coil** method, a reactance coil is introduced in the current circuit, the reactance being varied by moving an iron core in and out of the coil. It is difficult to obtain low power-factors with this method unless a separate low-potential current circuit is used, and then there is danger of **wave-form distortion.**

**214. Measurement of meter torque.** The torque is measured under normal conditions at full load by measuring the force in grams exerted at the edge of the disc, or at the end of an arm attached to the shaft. This force may be measured by means of weights, a calibrated watch spring, or by utilizing the principle of the pendulum.* By measuring the radius of the disc or the arm in millimeters, the torque is obtained in millimeter-grams, the usual unit.

**215. Measurement of watt-hour meter losses.** The losses in the windings of c.c. meters are calculated from the resistances, as determined with continuous current by standard methods. The losses in alternating-current meters are measured directly with wattmeters, but great care is required because of the very small amount of power and the small power-factor.

**216. The standards for direct-current meter tests** may be ammeters and voltmeters, in portable or special laboratory types, or potentiometers; in alternating-current meter tests, use is made of indicating wattmeters. The time in measuring the meter speed is usually determined with stopwatches, reading to tenths of seconds. Where a large number of meters

* Agnew, P. G. Bureau of Standards Bulletin, 1911, Vol. VII, No. 1. (Reprint No. 145.)

Digitized by Google

are being adjusted, it is customary to use standardized or master watt-hour meters and thus eliminate the measurement of time and watts.

**217. Service tests of watt-hour meters.** There are two general methods of making tests on meters where they are installed; (a) with indicating instruments and a stop-watch and (b) with standard watt-hour meters (Par. 218).

In the **indicating-instrument method**, the time of a given number of revolutions at a known load is duly noted. The load on direct-current meters is measured with an ammeter and a voltmeter. In a modified form of this method, the load is an accurately standardized resistance and only a voltmeter is required, the watts being $W = E^2/R$, where $W$ = watts, $E$ = volt and $R$ = ohms resistance of load. In the case of alternating-current meters, the load is preferably measured with a wattmeter.

**218. The rotating-standard method of watt-hour meter testing** is the most used, because only one observer is required and it is more accurate with fluctuating loads. **Rotating standards** are watt-hour meters similar to standard house-type service meters, except that they are made with extra care, are usually provided with more than one current and one potential range, and are more portable. A pointer, attached directly to the shaft, moves over a dial divided into 100 parts, so that fractions of a revolution are easily read. This standard meter is used by connecting it in series with the meter to be tested; the accuracy of the latter is determined by the "switch" method or the "eye-and-ear" method.

**In the "switch" method** the register only (in direct-current standards), or the entire moving element (in alternating-current standards), is started at the beginning of a revolution of the meter under test, by means of a suitable switch, and stopped at the end of a given number of revolutions. The accuracy is determined by direct comparison of the number of whole revolutions of the meter under test with the whole revolutions, and a fraction, of the standard.

**In the "eye and ear" method,** the number of whole revolutions of the standard is compared with a whole number of revolutions, and a fraction, of the meter under test. The revolutions of the standard are counted by ear by means of a telephone receiver and an electrical contact on the shaft, while those of the test meter are observed by eye.

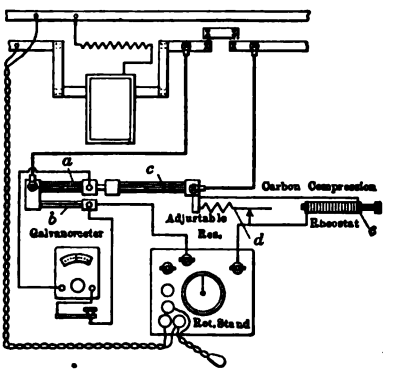

FIG. 78.—Connections for testing large watt-hour meters—Wheatstone bridge method.

**219. A Wheatstone-bridge method for testing large watt-hour meters** which cannot be conveniently cut out of service, and are on a load which fluctuates excessively, such as a railway load, has been developed by Messrs. Ingalls and Cowles.* The connections are shown in Fig. 78, where $a$ and $b$ are two fixed standard resistances or shunts, forming two arms of the bridge. The third arm is shown at $c$. A rotating standard with an adjustable fixed resistance $d$ and a carbon rheostat $e$ constitute the fourth arm. When $e$ is adjusted until the portable galvanometer shows zero deflection, the ratio of watts passing through the two meters is $a/(a+b)$.

**220. General precautions to be observed in testing watt-hour meters** are as follows: (a) The test period should always be sufficiently long and a sufficiently large number of independent readings should be taken to insure the desired accuracy. In service tests, the period preferably should be not less than 30 sec. and the number of readings not less than three. In laboratory tests, 100-sec. periods and five readings are preferable. (b) Capacity of the standards should be so chosen that readings will be taken at reasonably high percentages of their capacity, in order to make observational or scale errors as small as possible. (c) Where indicating instruments are used on a fluctuating load, their average deflections should be estimated in such a manner as to include the time of duration of each deflection, as well as the magnitude. (d) Instruments should be so connected that neither the standards nor the meter being tested are measuring the potential-circuit loss of the other, that the same potential is impressed on both, and that the same load current passes through both. (e) When the meter under test has not been previously in circuit, sufficient time should be allowed for the temperature of the potential circuit to become constant, preferably not less than 10 min.; this is important with direct-current meters, especially in the case of rotating standards. In some types of the latter, special provision is made for rapid heating. (f) Guard against the effect of stray fields by locating the standards and arranging the temporary test wiring in a judicious manner.

**221. Meter constants.** The following definitions of various meter constants are taken from "Code for Electricity Meters."*

**Register constant** is the number by which the register readings must be multiplied to obtain the registration. They are ordinarily used only on large-capacity meters and are marked on the register.

**Gear ratio** is number of revolutions of the rotating element per revolution of the first dial hand.

**Watt-hour constant** is the registration reduced to watt-hours per revolution of the rotating element. It has a definite value for each type and rated capacity of meter.

**Watt-second constant** is the registration reduced to watt seconds per revolution of the rotating element. It is equal to watt-hour constant multiplied by 3,600.

**Test constant** is the constant assigned by the manufacturer for use in the test formula for his meter.

**222. Testing formulas.** The accuracy of a watt-hour meter is the percentage of the total energy passed through a meter which is registered on the dials. Accuracy in per cent. = meter watt-hours × 100/true watt-hours. The value of one revolution having been assigned by the manufacturer, the meter watt-hours = $K_h \times R$, where $K_h$ = watt-hours per revolution or watt-hour constant and $R$ = revolutions in $S$ seconds. The corresponding power in watts is $P = (3{,}600 \times R \times K_h)/S$ = meter watts and 100 × meter watts/actual watts = per cent. accuracy. This is the standard formula for watt-hour meters.

**223. Manufacturers' formulas for meter watts.** When the test constant $K$ differs from the watt-hour constant, $K_h$, the formula is changed accordingly as follows:

| Manufacturer | $K$ in terms of $K_h$ | Manufacturers' formula for meter watts |
|---|---|---|
| Columbia | $K = 3{,}600\ K_h$ | $W = R \times K/S$ |
| Duncan | $K = 60\ K_h$ | $W = 60 \times R \times K/S$ |
| Fort Wayne | $K = 36\ K_h$ | $W = 100 \times R \times K/S$ |
| General Electric | $K = K_h$ | $W = 3{,}600 \times R \times K/S$ |
| Sangamo | $K = 3{,}600\ K_h$ | $W = R \times K/S$ |
| Westinghouse | $K = 3{,}600\ K_h$ | $W = R \times K/S$ |

$K_h$ = watt-hour constant, $K$ = test constant (marked on meter, usually on disc), $R$ = number of revolutions in $S$ seconds, $W$ = meter watts.

**224. Average accuracy of watt-hour meters.** The accuracy of a meter varies with the load, but it is often desirable to assign a value for the

* "Code for Electricity Meters." A. E. I. C. and N. E. L. A., 1912 ed., pp. 95 and 96.

Digitized by Google

average accuracy for all loads. Such a value obviously must be based on an arbitrary rule. The "Code for Electricity Meters" recommends the following:* When feasible; test the meter at 10 per cent. and 100 per cent. capacity of meter and at the normal load. Multiply the accuracy at normal load by three, add (to this) the accuracies found at each of the other two loads and divide the sum by five. This result is to be taken as the average accuracy. The "normal load" shall be taken as the percentage of the total rating of the connected load indicated in the table in Par. **226**.

**225. Table of Normal Loads of Watt-hour Meters†**

Per cent. of connected load which is equal to the "normal load" in calculation of average accuracy (Par. **224**)

| | |
|---|---|
| Residence and apartment lighting | 25 per cent. |
| Elevator service | 40 per cent. |
| Factories (individual drive) churches and offices | 45 per cent. |
| Factories (shaft drive) theatres, clubs, entrances, hallways and general store lighting | 60 per cent. |
| Saloons, restaurants, pumps, air compressors, ice machines and moving picture theatres | 70 per cent. |
| Sign and window lighting and blowers | 100 per cent. |

**226. Watt-hour meter specifications.** Probably the most extensive and authoritative specifications for the performance, installation, testing and maintenance of watt-hour meters in the United States are those included in the "**Code for Electricity Meters**" prepared by the Electrical Testing Laboratories under the joint direction of the Meter Committees of the A. E. I. Co.'s and the N. E. L. A. It is the basis of the rules issued by most of those state public utility commissions which have adopted regulations covering the subject of electricity meters. While scientific accuracy and correct technical principles are the basis of the code, the commercial phase of meter practice is not neglected. It covers the entire field of representative American meter practice including definitions, standards, specifications for meters and auxiliary apparatus, installation tests and maintenance.

**227. Ampere-hour meters** measure only quantity, that is, coulombs or ampere-hours, and therefore where they are used in the measurement of electrical energy, the potential is assumed to remain constant at a "declared" value, and the meter is calibrated or adjusted accordingly. Meters of this type may be divided into two general classes: electrochemical (Par. **228**) and electromotor (Par. **231**).

**228. Electrochemical ampere-hour meters** are essentially voltameters, because the quantity is measured by the amount of chemical decomposition of a substance caused by the passage of all or a part of the load current. In the **Edison chemical meter**, now obsolete, two zinc plates were immersed in a jar containing a zinc sulphate solution and connected in parallel with a shunt which in turn was in series with the load. The energy consumption was obtained by measuring the decrease in weight of the anode (positive) plate; 1.224 grams represented one ampere-hour.

**229. Modern types of electrochemical ampere-hour meters.** The principal modern types utilize the electrolysis of either water or mercury. The **Bastian meter** is an example of the former in which the change of the length of a column of water, as it is decomposed, is a measure of the quantity of electricity. A little caustic soda is added to decrease the resistance and a layer of oil is floated on top of the water to prevent evaporation and facilitate reading. A scale at the side of the tube is calibrated to read kilowatt-hours according to a "declared" voltage.

The **Wright meter** is the principal example of the **mercury type.** Metallic mercury is carried into a mercurous nitrate solution from a platinum cup anode and deposited in a platinum cup cathode, from which it flows into a fine tube. The height of this column is a measure of the energy consumption, a graduated scale being placed at the side of the tube. The electrodes are connected in parallel with a shunt, so that only a small portion of the load current passes through the solution. Provision is made for

---

* Page 99, 1912 Edition.

† "Code for Electricity Meters;" A. E. I. C. and N. E. L. A.; 1912 ed., p. 100.

Digitized by Google

easily emptying the mercury from the tube into the anode receptacle when the former becomes filled. This type of meter has been highly developed and inherent errors due to variation in temperature, concentration of the solution, level of mercury, effect of vibration, etc., are largely eliminated in the latest forms.

**230. The principal advantages of electrolytic-type ampere-hour instruments** are their low first cost and their simplicity, which results in low maintenance cost. These are important items to power companies serving very small customers, especially where the rates are low; and may outweigh the disadvantages, the principal among which are elimination of the potential element and relatively low accuracy.

**231. Electromotor ampere-hour meters** are similar to watt-hour meters, except that the field is produced by permanent magnets instead of electromagnets. The rotating element is geared to a registor which is calibrated in watt-hours for a given assumed voltage. There are two general types, the electromagnetic and the mercury flotation. The former is not made or used very much in this country.

The **Chamberlain and Hookum meter** is an example of the electromagnetic type. It employs a flat (pan-cake) armature winding mounted on an aluminum disc which also serves as the drag element. Connection is made to the circuit through a commutator and brushes in the usual manner. The armature is connected to a low-resistance shunt which is in series with the load.

The **mercury type** meter is well represented by the **Sangamo meter** which is practically the same as the Sangamo direct-current watt-hour meter (Par. **195**), the electromagnet being replaced by permanent magnets.

**232. Maximum demand meters.** Many methods of selling energy involve the maximum amount which is taken by the customer in any period of a prescribed length, that is, the maximum demand. Meters for measuring this demand variously utilize the expansion of air, the torque of a watt-hour meter, or a special recording device in connection with a standard watt-hour meter.

FIG. 79.—Diagram, Wright demand meter.

The **Wright demand meter** is a thermal instrument. It consists of a hermetically sealed U-shaped glass tube (Fig. 79), partly filled with a liquid. One leg *R* is connected near the top to a smaller graduated tube *T*. Around the top of the tube, *B*, is wound a resistance wire through which the current flows. The resultant heating of the air forces the liquid up the tube *R* and, if sufficient, over into the graduated tube. The air heats up gradually and the necessary **time lag** is thus obtained. According to the makers, if the overload continues 5 min., 80 per cent. of the load will be indicated; 10 min., 95 per cent.; and 30 min. 100 per cent.

**233. The General Electric demand meter** utilizes the principle of the induction watt-hour meter. The torque of the moving element is opposed by three long spiral springs, in series, and a powerful drag on the drag disc. This arrangement provides the necessary time lag. Two sweep-hands are provided on a dial. One is geared to the moving element, while the other is moved by the first one and left at the last position reached by it. This second pointer indicates therefore the maximum energy, until it is reset. The drag magnets and spiral springs being adjustable, the time lag can be adjusted through a considerable range. In this type of instrument, the demand is indicated at all times, as well as the maximum demand since the last setting.

**234. Recording maximum-demand meters.** In the **Minerallac Electric Co.'s "Printometer"** the kilowatt-hours indicated on a watt-hour meter are printed on a paper tape at intervals of any desired length. The hourly intervals are also indicated. It is separately mounted and can be electrically connected to any standard make of watt-hour meter. This device, while it indicates the time of maximum demand, is not an indicating instrument and considerable labor is involved in determining the maximum

Digitized by Google

demand. The **"Maxicator"** (Minerallac Co.), indicates the maximum demand with a sweep-hand. The **"Graphometer,"** (Minerallac Co.), produces a graphic record of the demand.

## CURVE-DRAWING INSTRUMENTS

**235. Curve-drawing or recording instruments** are essentially indicating instruments so arranged that a permanent, continuous record of the indication is made on a chart. They are made for recording all electrical quantities that can be measured with indicating instruments: current, potential, power, frequency and power-factor. Here the fundamental principles are, in general, those of standard indicating instruments, with the addition of a suitable recording mechanism. The two general classes are those in which the record or chart is made directly by the moving element and those in which it is made by a separate mechanism. In all types the chart is driven by a clock mechanism which is entirely separate from the instrument proper.

**236. Direct recording type.** Examples of this class are Bristol, General Electric and Esterline meters. The distinguishing feature of the Bristol instrument is the use of a circular chart. The direct-current ammeters and voltmeters employ a stationary coil or solenoid, the moving element being a soft-iron armature working against flat springs. The alternating-current instruments employ the electrodynamometer principle, with one movable coil and one stationary coil. Suitable provision is made for multiplying the armature movement, and damping is obtained with a vane immersed in oil. These instruments are extremely simple and relatively inexpensive. The sensitiveness is seriously affected by pen friction and where high sensibility is essential, a smoked chart with a very light pointer is used instead of the usual paper chart with pen and ink.

The principle of General Electric alternating ammeters is shown in Fig. 80, where *AA* are fixed coils connected in series, and *B* is a soft-iron armature upon which the field acts and produces a torque, and which carries the pen. The chart is a continuous straight one, moving from 1 in. to 12 in. per hour, as desired. The record is made in the form of a straight line on rectangular coordinates. The pen in this instrument carries an ink-well and is self-inking.

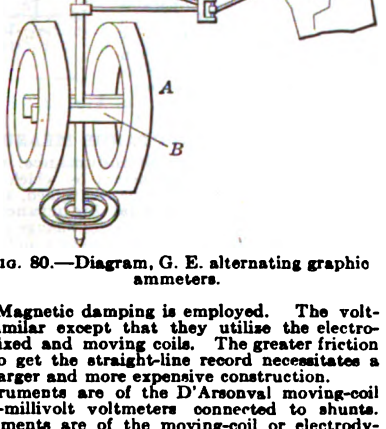

FIG. 80.—Diagram, G. E. alternating graphic ammeters.

Magnetic damping is employed. The voltmeters and wattmeters are similar except that they utilize the electrodynamometer principle, with fixed and moving coils. The greater friction and complication necessary to get the straight-line record necessitates a high torque and therefore a larger and more expensive construction.

Esterline direct-current instruments are of the D'Arsonval moving-coil type. The ammeters are 50-millivolt voltmeters connected to shunts. The alternating-current instruments are of the moving-coil or electrodynamometer type. The record is a straight-line one, made with a pen inked by siphon action from a stationary well. These instruments are made in portable as well as in switchboard form.

**237. Where pen friction is particularly objectionable,** as in low-reading millivoltmeters, the indicator is so arranged that it is in contact with the chart for only an instant at a time. In one form of Bristol instruments, a lever presses the end of the pointer against a smoked chart once

Digitized by Google

a minute, the pointer being perfectly free in the interim. The record is therefore a succession of dots. In other types of instruments, an inked thread or ribbon is interposed between the pointer and the paper chart.

**238. The Westinghouse recording instruments** are the principal example, in American practice, of the class where the recording mechanism is separate from the instrument proper. The moving element, by means of contacts, operates a relay which in turn operates the recording mechanism. Thus the moving element does not have to produce a large torque, while ample power can be applied to the recording mechanism, and hence friction does not affect the sensitiveness of the instrument. The direct-current instruments employ the D'Arsonval principle, using two sets of coils and magnets, astatically arranged. The alternating-current instruments use the principle of the Kelvin balance. Fig. 81 shows the scheme as employed in a voltmeter.

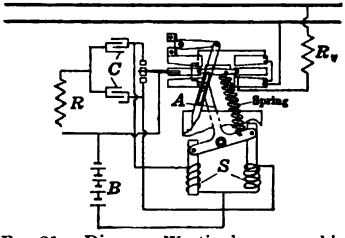

FIG. 81.—Diagram, Westinghouse graphic voltmeter.

**239. The Callender recorder** made by the Cambridge Scientific Instrument Co. employs the principle of a slide-wire bridge (Fig. 82) in which the resistance of one arm, $X$, varies with the current, potential or power to be measured. As soon as the bridge is unbalanced, a D'Arsonval galvanometer operates a relay, $r$ or $r'$, which moves a contact, $c$, along the slide wire $s$, until balance is restored, when the relay circuit opens. This contact also carries the recording pen, which leaves an ink record on a rectilinear chart.

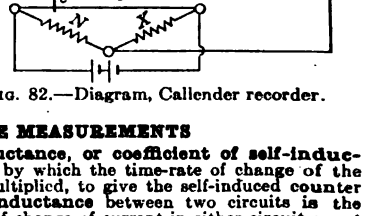

FIG. 82.—Diagram, Callender recorder.

## INDUCTANCE MEASUREMENTS

**240. General. The self-inductance, or coefficient of self-induction,** of a circuit is the constant by which the time-rate of change of the current in the circuit must be multiplied, to give the self-induced counter e.m.f. Similarly, the **mutual inductance** between two circuits is the constant by which the time-rate of change of current in either circuit must be multiplied to give the e.m.f. thereby induced in the other circuit. Self-inductance and mutual inductance depend upon the shape and dimensions of the circuits, the number of turns and the nature of the surrounding medium.

**241. Standards of inductance** are usually simple coils of copper wire suitably mounted on a non-conducting, non-magnetic frame. The turns are held rigidly in place by shellac, paraffine or other insulating medium. Inductance standards are made in single units like standard resistances, or in combinations, with plug connections, like a subdivided condenser or a resistance box. In the Ayrton-Perry **variable standard** there are two concentric coils, one fixed and the other movable. When connected in series these coils form a variable inductance, the value of which at any relative position is read from a circular scale at the top. Additional range is secured by connecting sections of the two coils in series-parallel combinations by means of plugs.

**242. Methods.** The most commonly employed methods of measuring inductance are (a) Wheatstone-bridge methods, where the inductance is determined by comparison with a known inductance or known capacity; and (b) impedance methods where the inductance is determined by calculation from measurements made with alternating current.

Digitized by Google

**243. In Wheatstone-bridge methods** a varying current must be employed. The potential drops, with steady current, are proportional to the resistances, whereas with a varying current the drops are proportional to the inductance, because $e = L\partial i/\partial t$, where $L$ = inductance and $e$ = e.m.f. induced by the current varying at the rate $\partial i/\partial t$.

**244. When the detector is an ordinary D'Arsonval galvanometer** the current may be varied by simply opening and closing the battery circuit, the galvanometer circuit being left closed; or a **secohmmeter** may be employed which rapidly reverses the current going into the bridge and simultaneously rectifies the galvanometer current, so that the latter is used as in ordinary bridge measurements. The current may also be rapidly interrupted with an induction-coil interrupter with a telephone receiver as the detector.

**245. A method in which a standard inductance is used** is shown in Fig. 83. If a continuous current is used, the bridge is first balanced with a steady current by adjusting $r_3$ and $r_4$, and again balanced with transient currents (battery key opened and closed) by adjusting $r_1$ and $r_2$; the bridge is then rebalanced with steady current, and again for transient currents, the process being repeated until the bridge is perfectly balanced under both conditions. At complete balance $L = L_s r_2/r_1$; where $L$ = inductance being measured, and $L_s$ = standard inductance. $L$ will be in the same units as $L_s$.

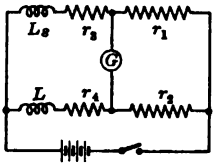

FIG. 83.—Inductance measurements with standard inductance.

**246. Use of Vreeland oscillator.** Small inductances, as well as large ones, may be measured with special convenience, accuracy and rapidity by this method (Par. **245**) if a source of high-frequency, sine-wave alternating current is available. A very satisfactory apparatus for this purpose is a Vreeland oscillator,* which delivers an absolutely pure sine-wave having a frequency which can be varied from a few hundred to about 2,000 cycles per second. It is operated from continuous current and is entirely static, the alternating current being derived from a circuit in which oscillations are set up by the rapid shifting of a mercury arc back and forth between two anodes. A telephone can be used as the detector, with a high degree of sensibility.

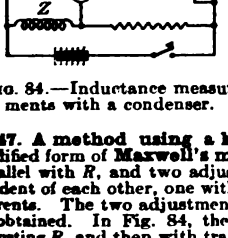

FIG. 84.—Inductance measurements with a condenser.

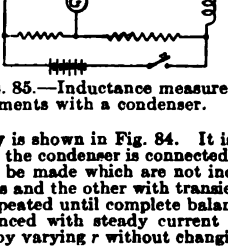

FIG. 85.—Inductance measurements with a condenser.

**247. A method using a known capacity** is shown in Fig. 84. It is a modified form of **Maxwell's method** in which the condenser is connected in parallel with $R$, and two adjustments have to be made which are not independent of each other, one with steady currents and the other with transient currents. The two adjustments have to be repeated until complete balance is obtained. In Fig. 84, the bridge is balanced with steady current by adjusting $R$, and then with transient currents by varying $r$ without changing the first adjustment. At balance,

$$L = \frac{Cr^2R_1}{R}10^{-6} \quad \text{(henrys)} \qquad (26)$$

* *Physical Review*, 1908, Vol. XXVIII, p. 286.

Digitized by Google

where $L$ = inductance of $Z$ in henrys, $r$ = ohms in parallel with $C$, $C$ = capacity of condenser in micro-farads, $R$ = total ohms of bridge arm to which condenser is connected and $R_z$ = ohms of $Z$.

**248. A similar method (Par. 247)** is indicated in Fig. 85 in which the adjustments are independent of each other, the bridge being first balanced with a steady current and then with a transient current by adjusting $r$ as in Fig. 84. At balance,

$$L = Cr^2 10^{-6} \quad \text{(henrys)} \qquad (27)$$

where $L$ = inductance of $Z$ in henrys, $C$ = capacity of the condenser in micro-farads and $r$ = ohms in parallel with $C$.

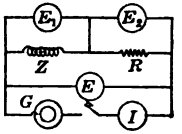

FIG. 86.—Inductance measurements—connections for three-volt-meter method.

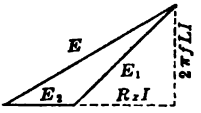

FIG. 87.—Inductance measurements—vector diagram for three-volt-meter method.

**249. Impedance methods of measuring inductance** are based on the law of the impedance of a circuit carrying sine-wave alternating current and containing only inductance and resistance, that is,

$$Z = \frac{E}{I} = \sqrt{R^2 + (L2\pi f)^2} \text{ or } L = \sqrt{\frac{E^2 - I^2R^2}{(2\pi fI)^2}} \quad \text{(henrys)} \qquad (28)$$

where $L$ = inductance in henrys, $E$ = drop in volts, $I$ = current in amperes, $R$ = resistance in ohms, and $f$ = frequency in cycles per sec. Obviously, due allowance should be made for the voltmeter current where its magnitude is sufficiently important.

**250. In the three-voltmeter method,** the inductance to be measured is connected in series with a non-inductive resistance as shown in Fig. 86.

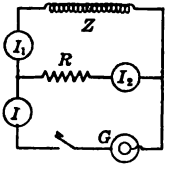

FIG. 88.—Inductance measurements—connections for three-ammeter method.

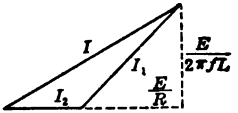

FIG. 89.—Inductance measurements—vector diagram for three-ammeter method.

The current, $I$, is measured, also the total volts, and the volts across the inductance $Z$ and the resistance $R$. From these readings a triangle is constructed, Fig. 87. If $R$ is known, the quantity $2\pi fLI$ can be calculated from the triangle. If $R$ is unknown, $2\pi fLI$ can be obtained by graphical construction. $I$ and $f$ being known, $L$ is obtained by calculation.

**251. The three-ammeter method** is similar. The connections are shown in Fig 88, and from the three currents, Fig. 89 is constructed. The e.m.f., $E$, can be measured directly or, if $R$ is known, by calculation from the relation $E = RI_2$. Hence $L$ can be obtained from the quantity $E/2\pi fL$.

**252. In circuits containing iron the inductance varies with the frequency and with the current;** hence alternating current of known frequency and intensity must be used. In such cases a bridge method with a standard inductance is convenient. A vibration galvanometer, a

Digitized by Google

synchronous contactor or a separately excited electrodynamometer can be used as the detector. The bridge is first balanced for resistance (that is, balanced for bridge-arm drops in phase with the supply current) and then for inductance (bridge-arm drops 90 deg., from the phase of the supply current).

**253. The mutual inductance, $M$, between two coils may be measured by several methods,** as follows:

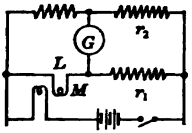

FIG. 90.—Mutual inductance measurements with inductance of one coil known.

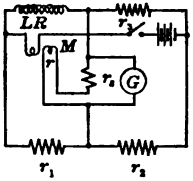

FIG. 91.—Mutual inductance measurements with known self inductance.

(a) **When the inductance, L, of one coil is known.** The connections are shown in Fig. 90. The bridge is balanced as in inductance measurements for both steady and transient currents. Then

$$M = \frac{-Lr_2}{(r_1+r_2)} \tag{29}$$

$M$ and $L$ are in same units, $r_1$ and $r_2$ in ohms.

(b) **By comparison with a known self-inductance.** Connect as in Fig. 91. First balance for steady currents; then balance for transient currents by adjusting $r_s$. Then

$$M = -L\frac{r_1(r_s+r)}{(R+r_1)^2} \tag{30}$$

where $r$ = resistance of secondary or mutual inductance $M$, and $R$ = resistance of self-inductance, $L$. M is in same units as L.

(c) **By comparison with a known capacity.** Connected as in Fig. 92. Balance as before for steady and transient currents by adjusting $r_1$ and $r_2$. Then

$$M = Cr_1r_2 10^{-6} \quad \text{(henrys)} \tag{31}$$

where $M$ = mutual inductance in henrys, $C$ = capacity in microfarads.

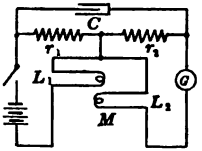

FIG. 92.—Mutual inductance measurements with known capacity.

(d) **By connecting the secondary in series with a ballistic galvanometer** and noting the quantity, $Q$, in coulombs, discharged into the galvanometer when the primary circuit is closed through a known resistance, of $R$ ohms, the steady value of the current being $I$ amperes. Then $M = QR/I$ in henrys. The quantity is determined from the galvanometer constant, or more directly, by calibrating the galvanometer with a standard condenser.

## CAPACITY MEASUREMENTS

**254. General.** The electrostatic capacity of two conductors separated by a dielectric depends upon the surface area of the conductors, the distance between them, the character of the dielectric, the temperature and the pressure.

**255. Condensers** are groups of conductors separated by insulation and especially constructed to have a known capacity. Commercial forms are generally made of sheets of tin foil separated by mica or paraffined paper, alternate layers of tin foil being connected to the same terminal. One box may contain one or more of these groups, with plug or other arrangements for connecting them in various series or parallel combinations.

Digitized by Google

**256. The capacity of a group of condensers in series is:**

$$C = \frac{1}{\frac{1}{C_1}+\frac{1}{C_2}+\frac{1}{C_3}+\ldots\ldots\frac{1}{C_n}} \qquad (32)$$

When connected in **parallel**,

$$C = C_1+C_2+C_3+\ldots\ldots C_n \qquad (33)$$

**257. In high-grade standard condensers**, the aim is to reduce the absorption, the dielectric hysteresis and the ohmic losses to a minimum. **Commercial standards** are made with tin-foil and high-grade mica, bound together under high pressure. **Primary standards**, however, are made with air as the dielectric, in which absorption and leakage are nil.

**258. Methods.** Electrostatic capacity measurements are made by bridge methods (Par. **259**), with a ballistic galvanometer (Par. **260**), by loss of charge (Par. **262**), and by impedance methods (Par. **263**).

**259. A bridge method** of measuring capacity is shown in Fig. 93. The ratio, $r_1/r_2$, or the standard condenser (if adjustable), is adjusted until the bridge is balanced; with an ordinary D'Arsonval galvanometer this condition is indicated when there is no "kick" as the reversing switch is changed from one position to the other. If interrupted currents or high-frequency alternating currents are used, with a telephone receiver, balance is indicated by silence in the receiver. Then $C_2 = C_1r_1/r_2$. The resistance should be non-inductive, anti-capacity and relatively large—several hundred ohms. Obviously, maximum sensibility is obtained when $C_2$ and $C_1$ are about equal. By employing a Vreeland oscillator (Par. **246**) and an adjustable air or oil condenser, small capacities can be very accurately measured by this method.

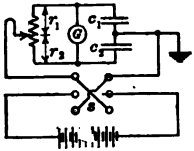

FIG. 93.—Capacity measurements, bridge method.

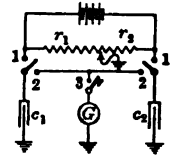

FIG. 94.—Capacity measurements, method of mixtures.

**260. In the ballistic galvanometer method**, the deflection is noted when the unknown capacity is discharged through it, immediately after having been charged at some known potential. A reading is then obtained with a standard condenser, the deflection being made about the same as before, by varying the capacity or the charging potential. The capacity can then be computed from the relation $d/d_1 = CE/C_1E_1$; where $d$, $d_1$, $C$, $C_1$, and $E$, $E_1$ are the respective deflections, capacities and potentials. This method is best suited to relatively large capacities, such as lead-covered, paper-insulated cables, etc.

**261. The Thomson method of mixtures** is shown in Fig. 94, where $c_1$ is a cable, transmission line or other capacity to be measured, and $c_2$ is a standard condenser. First the switches are closed at 1, 1, and the condensers charged to potentials corresponding to $r_1$ and $r_2$ respectively. After complete charge (a cable may require several minutes), the switches are shifted to 2, 2 and the charges equalised. If, then, the switch at 3 is closed, the deflection of the galvanometer will be proportional to the difference of the charges. This operation is repeated with various ratios $r_1/r_2$ until there is no deflection. Then $c_2 = c_1r_1/r_2$.

**262. In the loss of charge method**, Fig. 95, the condenser to be measured is first completely charged by moving switch $b$ to $a$, and then immediately discharged through a ballistic galvanometer by moving $b$ to $c$. The condenser is again charged and allowed to discharge through a known high

Digitized by Google

resistance, $R$, a given number of seconds, $t$, before being connected to the galvanometer a second time. The capacity in microfarads is

$$C = \frac{t}{R \log_{10} d_1/d_2\, 2.303} \quad \text{(microfarads)} \quad (34)$$

where $d_1$ = first deflection, $d_2$ = second deflection and $R$ = resistance in megohms. This method is applicable only where the resistance of the condenser being measured is very high, such as porcelain insulators.

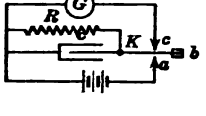

FIG. 95.—Capacity measurements, loss of charge method.

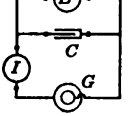

FIG. 96.—Capacity measurements, impedance method.

**263. In the impedance method,** the capacity is computed from the reactance as measured with an ammeter and a voltmeter, with alternating current of known frequency as shown in Fig. 96. Then

$$C = \frac{I}{2\pi f E}(10^6) \quad \text{(microfarads)} \quad (35)$$

where $C$ = capacity in microfarads, $E$ = volts, $I$ = amperes, and $f$ = frequency in cycles per second. Unless the voltmeter is an electrostatic instrument it should be disconnected when taking current readings. With small capacities, where $I$ is small, care should be taken that the high inductance of a low reading ammeter does not introduce an error. The capacity given by this method depends upon the wave form. Therefore the test should be made from the circuits to which the apparatus being measured will be connected in service.

**264. The specific inductive capacity** of materials is the ratio of the capacity of a condenser with the given material as a dielectric to that of the same condenser with air as a dielectric. In the case of solids in the form of sheets or plates, a condenser is readily made by attaching similar square or circular pieces of tin-foil of known area to opposite sides of the specimen and measuring the capacity by one of the methods described. Care should be taken that there is no deflection when the condenser has no charge. Certain materials in thin, sheet form may show a deflection, due to the galvanic action of the paste used to apply the tin-foil.

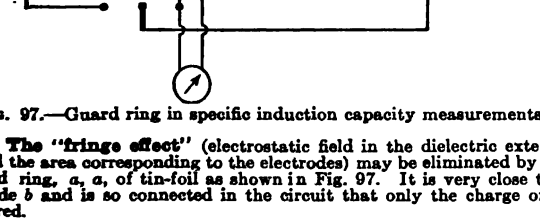

FIG. 97.—Guard ring in specific induction capacity measurements.

**265. The "fringe effect"** (electrostatic field in the dielectric extending beyond the area corresponding to the electrodes) may be eliminated by using a guard ring, $a$, $a$, of tin-foil as shown in Fig. 97. It is very close to the electrode $b$ and is so connected in the circuit that only the charge on $b$ is measured.

**266. The capacity of an air condenser** is $C = A/4\pi t \times 9 \times 10^5$, where $C$ = capacity in microfarads, $A$ = area in square centimeters and, $t$ = thickness of layer of air in centimeters.

## WAVE-FORM MEASUREMENTS

**267. Methods.** The instantaneous variations of current and potential in a circuit are measurable by step-by-step methods (Par. **268**), and with the oscillograph, (Par. **271**.) The former is applicable only where the current and the potential are strictly periodic and recurrent, as in a normal alternating-current circuit. The oscillograph can be used under all conditions, but is especially applicable to measurements of transient phenomena (Par. **268**), such as those which occur during switching operations on direct-current and alternating-current circuits. Where the wave form is to be analysed, the former is the more convenient and accurate.

**268. A convenient "step-by-step" arrangement** is shown in Fig. 98. The contact device consists of two slip-rings and a four-part commutator. One slip-ring is connected to one terminal of the source, the other to a voltmeter, and the commutator to a condenser. By means of this arrangement, the condenser after being charged is immediately discharged through the voltmeter. These impulses follow each other so rapidly that a steady deflection is obtained, and by suitable adjustment of $R$ and $r$ on continuous current, the voltmeter may be made direct reading. The instantaneous values at any point on the wave are obtained by shifting the brushes around the shaft. The switch is closed at 1 for voltage measurements and at 2 for current measurements.*

The General Electric **wave meter** operates on this principle. The driving motor is an eight-pole synchronous motor connected to the source being measured and there are eight segments (one per pole), instead of only one. Suitable provision is made for tracing the wave form on a photographic plate.

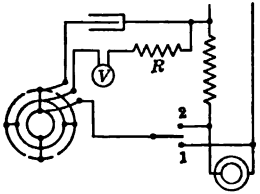

FIG. 98.—Wave-form measurements, "Step-by-step" method.

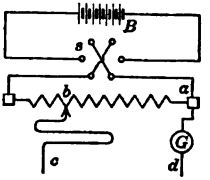

FIG. 99.—Wave-form measurements, zero method.

**269. In the zero method** shown in Fig. 99, the e.m.f. of a battery $B$ is opposed to the potential across $c$ and $d$, which are connected to the contact devices described above. The contact point, $b$, is adjusted until $G$ shows no deflection; then the length $ba$ is a measure of the e.m.f. $G$ may be a portable galvanometer, or a telephone in conjunction with a slide wire and a contact stylus as used in the Sage ohmmeter (Par. **139**).

**270. The wave form of a high-tension wave** may be obtained by using the device shown in Fig. 102 and described in Par. **277**. The indication of the electrostatic voltmeter is obtained at different angular positions of the brushes on the synchronous commutator, from which the wave form may be plotted.

**271. The oscillograph** is a form of galvanometer in which the natural period of the moving system is so small that the deflections will always be proportional to the instantaneous value of the current flowing through the coil. The indicator is a beam of light from an arc lamp, reflected from an extremely small mirror attached to the moving system. The path of the beam is determined visually or photographically. Recurrent or periodic waves may be rendered stationary and therefore visible by suitable optical systems as indicated below. Transient phenomena must be photographed by an instantaneous process.

**272. In the moving-iron type of oscillograph,** first proposed by

* See also Frederick Bedell. "Condenser Current Method for the Determination of Alternating Wave Form," *Electrical World*, 1913, Vol. LXII, p. 378.

Digitized by Google

**Blondel,*** a very small piece of soft iron is suspended in a strong magnetic field, thus forming a polarised magnet. Near this strip are placed two small coils, which carry the current to be investigated. Because of its very small period, this magnet will follow every variation in the current.

**273. The moving-coil type of oscillograph** developed by **Duddell** consists of a single-turn coil formed by passing a phosphor-bronze strip over a pulley suspended by a spring, and between the poles of a powerful electromagnet as shown in Fig. 100. It has a much lower inductance than the moving-iron type and therefore a wider range of application. This type is now in most general use and in this country is prominently represented by the General Electric oscillograph, a very simple, rugged and practical instrument. Three elements or vibrators are usually provided in the latter, and three waves may be taken simultaneously. The electromagnets are wound for 110 volts, at which excitation the sensibility of the vibrators is of the order of 0.005 amp. per millimeter deflection. The moving system is immersed in a well, with a glass front, and filled with oil to dampen the oscillations. The natural frequency is of the order of 5,000 vibrations per second.

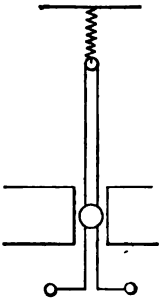

FIG. 100.—Element of moving coil type of oscillograph.

**274. Various receiving devices** are used to render the wave visible to the eye. One scheme employs a rotating mirror driven by a synchronous motor connected to the circuit being tested. In the General Electric oscillograph the beam of light from the arc, *a*, Fig. 101, is concentrated by a lens, *b*, upon the mirror, *l*, of the vibrator, which is oscillating about an axis perpendicular to the beam. The mirror, *m*, is driven by a cam, *d*, which gives a comparatively slow forward stroke and a quick backward stroke. When this mirror is stationary the image of the reflected beam at *s* is a straight line the length of which is proportional to twice the angular deflection of the vibrator. If the mirror is rotated forward, the image at *s* is spread out thus tracing a wave. The wave is made to appear stationary by automatically cutting off the light on the return stroke of *m* by means of the shutter *e*.

**275. Permanent oscillograph records** may be made by tracing the wave on transparent paper or tracing cloth placed on the screen, *s*, referred to above (Par. 274). For making photograph records, or oscillograms, the visual attachment is replaced by a light-proof cylinder containing the film and fitting over an opening in the oscillograph case through which the beam of light passes to the film. The film is unrolled from one spool on to another and past the opening by a motor-driven mechanism; its speed is adjusted to suit the conditions. In the case of transient phenomena it is often found necessary to arrange special devices to start the film automatically at the proper time in order to get the phenomena on the film. A record of elapsed time in direct-current phenomena can be obtained by connecting one of the elements to a source of alternating current of known frequency, or by means of an electrically driven tuning-fork of known frequency. A small mirror mounted on the end of one prong and so placed that it will reflect a part of the beam, will give an excellent time record. The scale of ordinates is obtained by calibration on continuous current, the deflection of the spot of light corresponding to a known current, or voltage, being noted.

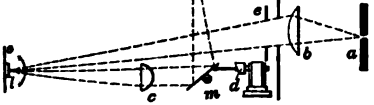

FIG. 101.—Visual attachment, G. E. oscillograph.

**276. Standard wave form.** It is desirable that commercial alternating-current wave forms be as near a sine curve as possible in order to

* Blondel, A. E. *Comptes Rendus*, 1893, Vol. CXVI, p. 502.

Digitized by Google

reduce iron losses, excitation currents, charging currents, etc., to a minimum. The present A. I. E. E. standard method of measuring the deviation from a sine curve is simply to measure the greatest difference between corresponding ordinates at any point along the axis of abscissæ. It has been proposed* to replace this method by another in which the increase in condenser charging-current with the given wave, over the charging current with a pure sine-wave, will be determined. This is a simple and sensitive method of determining the presence of harmonics, since the charging current of a condenser varies with the square of the frequency. The current for a given condenser on a sine-wave can be calculated from the relation $I = EC \times 2\pi f$, where $I$ = current in amperes, $E$ = potential in volts, $C$ = capacity in microfarads and $f$ = cycles per second.

**277. In high-voltage testing** it is particularly important that the value of the maximum instantaneous voltage be available, because the stress to which insulation is subjected depends upon this value. When the wave is distorted, the maximum value and the ratio of the maximum to mean-effective (amplitude or peak factor) have to be obtained from a plot of the wave. This may be taken with a wave meter or with an oscillograph, preferably connected to a test coil in the high-tension winding or to the secondary of a shunt-type instrument transformer connected to the high-tension circuit.

**A method which can be used directly on the highest voltages**† is indicated in Fig. 102, where $C$ is a series of condensers connected across the high-tension circuit. The end condenser $C_1$ is grounded and connected in parallel with a commutator driven by a synchronous motor. The bars on the commutator are very narrow and are one polar space apart, so that contact is practically instantaneous. The brushes are shifted until the voltmeter indication is a maximum. The multiplying ratio is obtained from the ratio $(C+C_1)/C_1$. The instrument may be calibrated by noting the indication corresponding to the mean effective value, which is obtained with the motor stationary and the brushes resting on the bars. This indication is compared with a spark gap or other standard. The method assumes that the capacity of $V$ is negligible in comparison with $C_1$. Obviously the condensers can be dispensed with by connecting directly to a test coil on the high-tension winding.

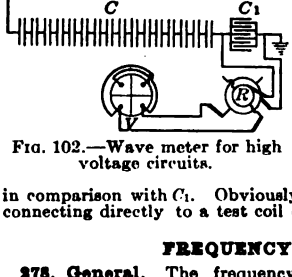

FIG. 102.—Wave meter for high voltage circuits.

## FREQUENCY MEASUREMENTS

**278. General.** The frequency of an alternating current is $f = nr/2$, where $f$ = frequency in cycles per second, $n$ = number of poles, and $r$ = revolutions per second. It may therefore be determined by measuring the speed of the generator supplying the circuit or the speed of a synchronous motor operated from the circuit.

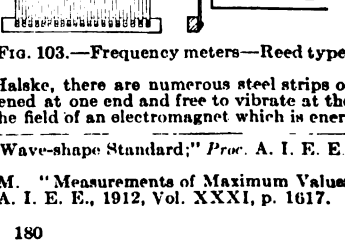

FIG. 103.—Frequency meters—Reed type.

**279. Frequency meters** indicate the frequency directly. In the **reed type** as made by Hartman and Braun or Siemens and Halske, there are numerous steel strips of different lengths, each rigidly fastened at one end and free to vibrate at the other. The strips are placed in the field of an electromagnet which is ener-

* Davis, C. M. "A Proposed Wave-shape Standard;" *Proc.* A. I. E. E., Feb., 1913, p. 235.

Digitized by Google

gised from the circuit to be measured, as shown in Fig. 103. The strips have different natural periods, and the one with a period corresponding to the alternations of the magnetic field will be set in vibration. The ends are turned up and painted white so that the particular reed in a row, which is vibrating, will be indicated by a white band or blur. Each reed is carefully adjusted to an exact period by attaching minute weights. These meters are made in various ranges and with reeds adjusted from 0.25 cycle to 2 cycles apart.

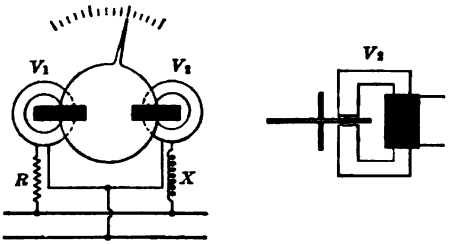

FIG. 103a.—Circuits in Westinghouse frequency meters.

**280. The Westinghouse frequency meter** consists of two voltmeter movements, mechanically so interconnected that they tend to rotate the pointer in opposite directions. A non-inductive resistance $R$ is connected in series with one movement, $V_1$ (Fig. 103a) and an inductance $X$ is connected in series with the other element, $V_2$. The apparent resistance of the inductive movement varies with the frequency and thus varies the amount of current taken by it. Therefore each frequency will cause the pointer to take up a different position.

**281. The Weston frequency meter** is shown in Fig. 104, where 1, 1 and 2, 2 are fixed coils, 90 deg. apart, and $c$, $c$ is the movable element consisting of a simple, soft-iron core mounted on a shaft, with no control of any kind. One coil, 2, 2, is connected in series with a non-inductive resistance, $R_2$, and the other coil, 1, 1, in series with an inductance, $X_1$. A second non-inductive resistance $R_1$ is connected in parallel with 1, 1 and $X_1$. A second inductance, $X_2$, is connected in parallel with 2, 2 and $R_2$. The soft-iron core takes up the position of the resultant field produced by the two coils. When the frequency increases, the current decreases in 1, 1 and increases in 2, 2, thus shifting the direction of the resultant field and the position of $c$, $c$ to which the pointer is attached. The opposite effect takes place when the frequency is decreased. The series inductance, $X$, serves merely to damp the higher harmonics.

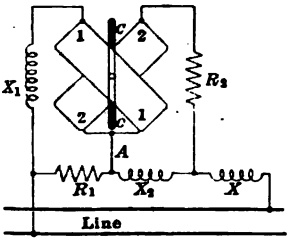

FIG. 104.—Circuits in Weston frequency meters.

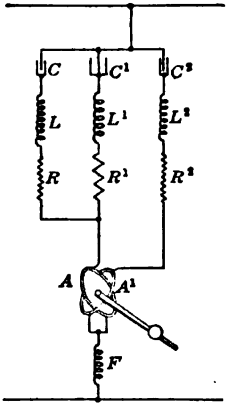

FIG. 105.—High sensibility frequency indicator.

**282. A very sensitive frequency indicator** is shown in Fig. 105, in

Digitized by Google

which the principle of resonance (Sec. 2) in an electrical circuit is employed.* In a 60-cycle instrument, one main circuit is adjusted for resonance at about 70 cycles, another at about 58 cycles and the third circuit at about 36 cycles. The latter two are connected in parallel, and then in series with coil $A$; the first circuit is in series with coil $A^1$, both coils being in series with the field $F$. With the centre of a 6-in. (15 cm.) scale marked for 60 cycles, half-scale deflection is obtained for a variation of only 5 cycles either way. It is possible to adjust the instrument for a full-scale range of only 1 cycle.

## SLIP MEASUREMENTS

**283. General.** The slip of a rotating alternating-current machine in per cent. is the difference between its speed and the synchronous speed, divided by the synchronous speed. It may be determined by noting the difference between the measured speed of the machine and the synchronous speed as calculated from the frequency and the number of poles. This method is obviously not accurate, because the result is a small difference between two relatively large quantities. It is therefore customary to measure the slip directly.

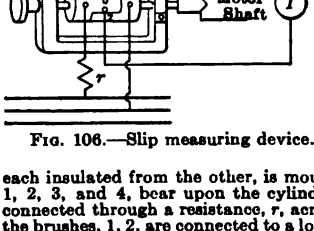

FIG. 106.—Slip measuring device.

**284. Dooley's method of measuring slip.** One form of device for indicating the slip of an induction motor† is shown diagrammatically in Fig. 106. A small cylinder made of conducting material, and in two parts, each insulated from the other, is mounted in a frame. Four small brushes, 1, 2, 3, and 4, bear upon the cylinder as shown. The brushes, 3, 4, are connected through a resistance, $r$, across one phase of the supply circuit and the brushes, 1, 2, are connected to a low-reading continuous-current ammeter, $I$. Each time the brushes, 1, 2, bridge the insulating strip as the cylinder rotates, the circuit is completed in alternate directions through the ammeter. The cylinder should have as many segments as the motor has poles. The ammeter will indicate a constant current at synchronous speed, and an oscillating current for any speed above or below synchronism, because the impulses of current through the brushes, 1, 2, will occur at the same point on the wave at synchronous speed, and at constantly advancing or retarding points for other speeds. Thus, the ammeter will be reversed each time the motor loses one-half of a cycle, and will reach a maximum positive value each time the motor loses one complete cycle. If the motor loses $n$ cycles per min., then the slip in per cent. $= 100n/60f$, where $f$ = frequency of the system in cycles per sec.

FIG. 107.—Slip measurements — Stroboscopic method.

**285. Stroboscopic method.** The device indicated in Fig. 107 does not require the measurement of frequency. A black disc with white sectors, equal in number to the number of poles of the induction motor, is attached with wax to the induction-motor shaft. It is observed through another disc having an equal number of sector-shaped slits and carried on the shaft of a small self-starting synchronous motor, in turn fitted with a revolution counter which can be thrown in and out of gear at will. If $n$ is the number of passages of the sectors, then $(n/n_s)/n_r$ = slip in terms of $s$ where $n_s$ = the number of sectors, and $n_r$ = the number of revolutions recorded by the counter during the interval of observation. For large values of slip the observations can be simplified by using only one sector ($n_s = 1$); then $n$ = the slip in revolutions.

**286. A direct-reading slip-measuring device** is shown in Fig. 108.

*D* is a carefully turned and hardened conical drum driven by the motor being tested, through a flexible shaft, *S*. The long screw, *H*, moves a carriage, *C*, parallel to the surface of *D*. This carriage carries a wheel *d*, also carefully turned and hardened, which has a line edge and is kept in contact at all times with the surface of *D* by means of a light spring. Thus it revolves with *D*. On the same shaft is a disc, *sd*, with alternate black and white sectors painted on it, the number of sectors being equal to the poles of the motor being tested. The diameter of *d* is made equal to that of the small end of *D*. At the setting corresponding to the small end of *D*, the scale along which the carriage moves is marked zero. This corresponds to synchronous speed. As the speed of *D* decreases, it is necessary to move *d* toward the large end of *D* in order to keep the speed of *d* the same as at synchronous speed. This distance is a measure of the slip. The synchronous speed of *sd* is indicated when it appears to stand still, when illuminated by an arc lamp connected to the same circuit to which the motor is connected. Thus, if *D* is 2 in. (5.1 cm.) in diameter at the small end, 2.5 in. (6.35 cm.) at the large end and 5 in. (12.7 cm.) long, slips from 0 to 20 per cent. can be measured with a precision within 0.2 per cent. A more sensitive detector consists of a commutator in place of *sd*, connected in series with a direct-current voltmeter and the circuit to which the motor is connected. The indication is a maximum at synchronous speed.

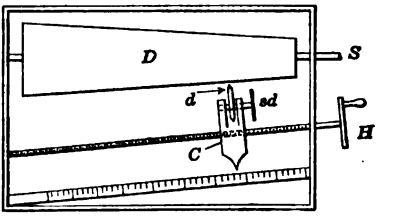

FIG. 108.—Slip measuring device.

**287. Synchronism indicators.** In order to connect any synchronous machine in parallel with another machine or system, the two voltages must be made equal and the machine must be synchronized, that is, the speed so adjusted that corresponding instantaneous values on the two waves are reached at the same instant, when they will be in exact phase. Furthermore, with polyphase machines, the direction of phase rotation must assuredly be the same. This, however, is usually made right once for all when the machines are installed, the phases being so connected to the switches that the phase rotation will always be correct.

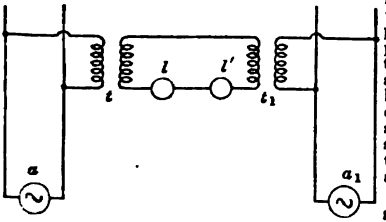

FIG. 109.—Connections for synchronising with lamps.

**288. The lamp method of synchronizing** is the simplest. The principle of lamp synchronizers is shown in Fig. 109, where $a$, $a_1$ are the sources being connected in parallel and $t$, $t_1$ are transformers, the secondaries of which are connected in opposition through incandescent lamps, $l$, $l_1$. When the two sources are in synchronism, the secondary e.m.fs. neutralise each other and the lamps will be "dark." As the phase difference increases, the current through the lamps will increase, reaching a maximum at 180 deg. of phase difference. If the secondary of one transformer is reversed, the lamps will be brightest at synchronism and dark at 180 deg. of phase difference. The former connection is preferable because the point of total "darkness" is more easily detected than the point of maximum "brightness."

A voltmeter may be substituted for the lamps by connecting it so that synchronism is indicated when the reading is a maximum. The disadvantage of this method is that it does not indicate which frequency is the higher. Synchronism indicators (Par. **287**) are instruments which not only overcome this objection, but indicate the point of synchronism more accurately.

**289. The principle of the Westinghouse synchroniser** is shown in Fig. 110, where a rotating field is produced by the coils, *M* and *N*, connected to the buses through the reactance *P* and the resistance *Q*, respectively. An iron vane *A*, free to rotate, is mounted in this rotating field and magnetised by the coil *C*, which in turn is connected across the incoming machine. As the vane is attracted or repelled by the rotating field from *M* and *N*, it will take up a position where this field is zero at the same instant that the field from *C* is zero. Hence the position at any instant indicates the difference in phase. When the two frequencies are different, this position is constantly changing and the pointer will rotate "fast" or "slow," coming to rest at the zero-field position when the frequencies are equal. In a larger type, the split-phase winding is placed on the movable member, similar to the arrangement shown in Fig. 111.

**290. The scheme of the Weston synchroscope** is shown in Fig. 112. There is no iron in

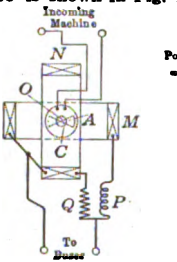

FIG. 110.—Circuits in Westinghouse synchroniser.

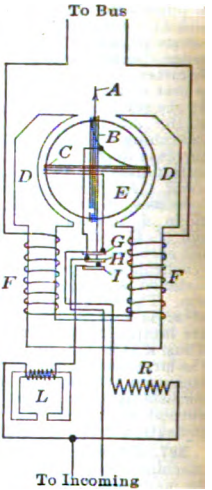

FIG. 111.—Circuits in G. E. synchroscope.

the instrument and the moving element is not allowed to rotate. The elements are practically the same as in an electrodynamometer wattmeter. The fixed coils, *F*, *F*, are connected in series with the resistance *R* and to the buses. The moving coil, *M*, is connected in series with a condenser *C* and the incoming machine. The two circuits are adjusted to exactly 90 deg.

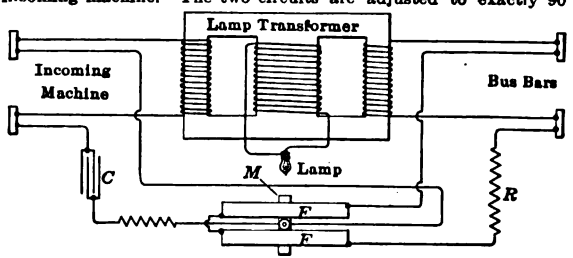

FIG. 112.—Circuits in Weston synchroscope.

difference in phase. At synchronism there is no torque and *M* is held at the zero position by the control spring. If the frequencies are the same, but there is a phase difference, a torque will be exerted and *M* will move to a position of balance at the right or left ("fast" or "slow"). If the frequencies are different, the torque will continually vary and the pointer will oscillate over the dial. A synchronizing lamp illuminates the scale simultaneously and the direction of apparent rotation indicates the faster machine.

**291. The General Electric synchroscope** operates on the same principle as the Westinghouse instrument (Fig. 111). The split-phase winding, *C*, *B*, is mounted on the movable element, *E*, the two coils being connected to the incoming machine through slip-rings.

## MAGNETIC MEASUREMENTS

**292. General. The strength of a magnetic field, $\mathfrak{H}$,** is measured in lines of magnetic force per square centimeter, or in gausses. In a long straight solenoid it is $4\pi NI/10l$, where $I$ = current in amperes and $N/l$ = turns per unit length. **Magnetic induction or flux density, $\mathfrak{G}$,** is measured in lines of magnetic induction per square centimeter, or in gausses. When the substance in which the field exists is non-magnetic, $\mathfrak{G} = \mathfrak{H}$ and the ratio $\mathfrak{G}/\mathfrak{H}$, or permeability, is $\mu = 1$. When the substance is magnetic, $\mathfrak{G}$ becomes much greater than $\mathfrak{H}$, due to the decreased magnetic resistance; in general it varies with $\mathfrak{H}$.

**293. The normal induction or $\mathfrak{G}$-$\mathfrak{H}$ curve** of a magnetic material is the curve plotted between the strength of the magnetic field existing in the material, $\mathfrak{H}$, and the magnetic induction, $\mathfrak{G}$, produced by that field, when the material is in a neutral or normal condition. **A permeability curve** is plotted between the permeability $\mu$ and $\mathfrak{G}$, or between $\mu$ and $\mathfrak{H}$.

**294. The hysteresis curve** is a curve plotted between $\mathfrak{G}$ and $\mathfrak{H}$, for various values of $\mathfrak{H}$ from a maximum value in the positive direction to a maximum value in the negative direction, and back again, or through a complete cycle of values. The ends of a hysteresis loop will lie in the normal induction curve.

**295. Magnetic measurements may be divided into two classes,** (1) those in which the strength of a magnetic field is determined (such as the earth's field, the field due to a conductor carrying a current, the field in the air gap of a magnet, etc.) and (2) those made to determine the properties of magnetic material.

**296. Field-strength measurements** may be made by induction methods, with an oscillating bar magnet (Par. 299), or with a bismuth spiral (Par. 300). In the induction method a coil of known turns and area is so arranged that it can be made to cut the field in a known area in a direction perpendicular to the field. The e.m.f. generated in the coil, and hence the field producing it, is determined from the quantity of electricity discharged through a ballistic galvanometer connected to the coil terminals.

In measuring the field strength in air gaps, the coil is so arranged that it can be moved quickly across the entire gap, or through a definite distance, by means of a spring or weight suddenly released. When there is sufficient space, a more accurate and convenient method is to rotate the coil through 180 deg. Very weak fields, such as the earth's field and that due to conductors, may be measured in this manner by using a sufficiently large coil.

**297. Formula for field strength.** The field strength in lines per square centimeter is

$$\mathfrak{H} = \frac{10^8 dkR}{xan} \qquad \text{(gilberts per cm.)} \qquad (36)$$

where $d$ = deflection, $k$ = constant of galvanometer in coulombs per scale division, $R$ = total resistance in galvanometer circuit, $n$ = turns in coil, $a$ = mean area of coil in square centimeters, $x$ = linear distance moved in centimeters or, when the coil is turned through 180 deg., $x = 2$.

**298. The Grassot fluxmeter** is a portable instrument with which magnetic flux may be read directly on a scale. It is essentially a ballistic galvanometer with the moving element replaced by a torsionless suspension so that it remains deflected. The instrument is connected to an exploring coil which is placed in the air gap to be measured. The flux is measured by noting the deflection when the magnetising circuit is either opened or closed.

**299. In the oscillating-magnet method,** a small simple bar magnet is suspended by untwisted silk fibres. The magnet is set to vibrating through an angle of about 5 deg. and the period of oscillation determined. The average of at least three observations should be taken. The field strength is

$$\mathfrak{H} = \frac{4\pi^2 K}{MT^2} \qquad \text{(gilberts per cm.)} \qquad (37)$$

Digitized by Google

where $K$ = moment of inertia computed from the mass and dimensions, $M$ = magnetic moment, and $T$ = period of oscillation. $M$ may be determined with a magnetometer, or by calibration in a known field (Helmholtz coil). This method is only suitable for weak fields, such as the earth's field. If mounted in a wooden box with a glass front, it will be protected from air currents and can be conveniently moved about when making magnetic surveys.

**300. Bismuth-spiral method.** The resistance of bismuth wire increases when placed in a magnetic field. This property is utilized by noting the increase in resistance of a flat spiral coil of bismuth wire when placed in the field to be measured, the leading-in wires being arranged non-inductively. The device is **calibrated** with known field strengths. It is particularly suitable for exploring small air gaps such as those in motors and generators.

**301. Measurement of magnetic properties.** The magnetic properties of iron and steel which are of most commercial importance are **normal induction** or **permeability, hysteresis loss** and **total losses** with alternating magnetizing forces of commercial frequencies.

**302. Normal-induction data.** The various methods are distinguished principally by the method employed to measure $\mathfrak{B}$, for in all methods $\mathfrak{H}$ is determined from the magnetizing coil. $\mathfrak{B}$ can be measured directly as in the **ballistic methods** or indirectly with **permeameters.**

**303. Ballistic methods** are usually employed in the more accurate measurements. The best-known methods are the **ring method,** the **divided bar** or Hopkinson, and the **double-bar double-yoke methods.** In all of these methods the flux is measured with a ballistic galvanometer connected to a test coil which is cut by the flux when the exciting current is reversed.

**304. The ring method,** devised by Rowland, is one of the earliest methods of measuring the permeability and the hysteresis of iron and steel.

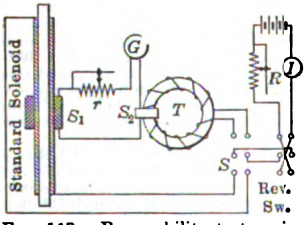

FIG. 113.—Permeability tests—ring method.

The connections are shown diagrammatically in Fig. 113, where $T$ is the test specimen. The latter is an annular ring, either solid or built up of punchings of sheet metal, with a diameter preferably 8 or 10 times the radial thickness. After covering with a thin layer of insulation, a test coil of very fine double-silk-covered wire is wound on a portion of the ring. The magnetising coil is wound over the test coil, and distributed uniformly over the entire ring; it is usually comprised of double-cotton-covered wire, of sufficient size to carry the maximum current without raising the temperature of the iron appreciably.

**305. The divided-bar method** devised by Hopkinson avoids the necessity of winding each specimen separately, permits the use of a more convenient test piece, and avoids the errors in ring specimens.* The device consists of a test piece, $BC$ (Fig. 114), in the form of a bar about 15 in. (38.1 cm.) long and 0.5 in. (1.27 cm.) diameter, which is divided at $A$ and inserted in a massive frame, $F$. The secondary coil, $S$, is so arranged that it will be thrown clear of the yoke by a spring when the part, $AB$, of the test bar is suddenly withdrawn. In calculating $\mathfrak{H}$, the length of the magnetic circuit is taken as that between the inside faces of the yoke, the reluctance of the yoke being considered negligible. This introduces an indeterminable

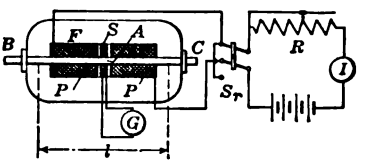

FIG. 114.—Permeability tests—divided-bar method.

* Lloyd, M. G. "Errors in Magnetic Testing with Ring Specimens;" Bureau of Standards, Bulletin, 1908, Vol. V, No. 3; p. 435.

Digitized by Google

error and, therefore, the method can be suitable only for rough measurements. The leakage error due to flux through the coil, but not through the bar, can be determined by preliminary test with a non-magnetic bar. The formulæ for $\mathfrak{H}$ and $\mathfrak{B}$ are $\mathfrak{H} = 4\pi NI/10l$ and $\mathfrak{B} = 10^8 dkR/an$, where $N$ = total turns of exciting coil, $I$ = exciting current in amperes, $l$ = length of magnetising coil in cm. ($NI/l$ = ampere-turns per cm.), $d$ = deflection, $R$ = total resistance of test coil circuit, $k$ = galvanometer constant, $a$ = area of specimen in square centimeter and $n$ = turns in test coil.

**306. The double-bar, double-yoke method** is the one **recommended** by the **American Society for Testing Materials.** It was devised by

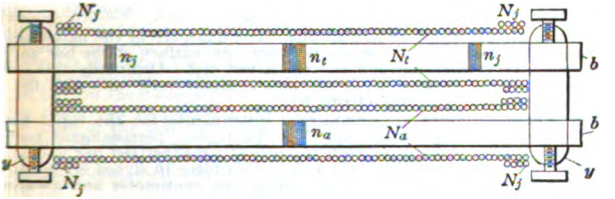

FIG. 115.—Permeability tests, double-yoke method.

C. W. Burrows* and is the standard method used at the **Bureau of Standards** for both solid and sheet specimens. Not only is the precision high, but the method is also rapid and convenient when the observer is experienced. The essential feature is the distribution of the magnetising winding in sections, which permits the independent adjustment of the magnetising force in various parts of the magnetic circuit. Thus the effect of non-uniform reluctance at joints, etc., can be overcome and the induction made uniform throughout the entire magnetic circuit. Exploring coils are placed at various positions so that the uniformity of the induction can be

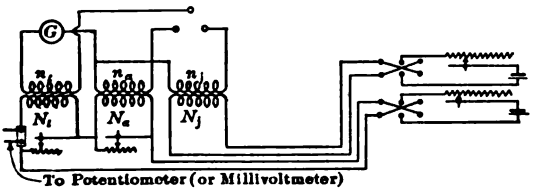

FIG. 116.—Connection diagram for double-yoke method.

tested. The scheme is shown in Fig. 115 where $b$, $b$ are two bars (standard size, 1 cm. diameter, 35 cm. long) one to be tested and the other an auxiliary bar of similar material. $Y$, $y$ are yokes of Norway iron about 15 cm. long and about 4 or 5 cm. diameter, into which the bars are clamped. The magnetomotive-force is applied in three sections: one coil, $N_t$, is placed over the test specimen; another, $N_a$, over the auxiliary rod; and the third, $N_j$, is divided into four parts, one near each joint. The corresponding exploring coils are $n_t$, $n_a$ and $n_j$. These coils all have the same number of turns, that is, $n_t = n_a =$ the two parts of $n_j$ in series. They are so connected to a switch that $n_a$ or $n_j$ may be connected through the ballistic galvanometer in opposition to $n_t$, thus providing a zero method of determining the condition of uniformity of flux. The scheme of connections is shown in Fig. 116. The magnetising coils are connected to special mercury-cup reversing switches so made that they can be operated simultaneously like the keys of a piano.

* Burrows, C. W. *Trans.* A. S. T. M., 1909, Vol. XI, p. 31.

**307. Procedure in double-bar double-yoke method.** The method of procedure is as follows: After demagnetising (Par. 221), the current in $N_1$ is adjusted to the value of $\mathfrak{H}$ required. The current in all magnetising coils is then simultaneously reversed several times to get the specimen in a cyclic condition, the current in $N_2$ and $N_3$ being adjusted during the process until the flux is uniform as indicated by zero deflection when $n_2$ and $n_3$ are successively opposed to $n_1$. The galvanometer is connected to $n$ and the deflection noted when the current in the various magnetising coils is reversed simultaneously. Then

$$\mathfrak{H} = \frac{4\pi NI}{10\,l} \qquad \text{(gilberts per cm.)} \qquad (38)$$

$$\mathfrak{B} = \frac{10^8 dkR}{2an} - \left(\frac{a-A}{A}\right)\mathfrak{H} \qquad \text{(gauses)} \qquad (39)$$

The units are the same as in Par. 305. The quantity in the parenthesis is the correction factor for the space between the surface of the bar and the test coil. $A$ = area of bar and $a$ = area of test coil. Ordinarily this correction is very small because the brass tube is made very thin and the test coil is wound under the magnetising coil.

**308. Permeameters** are commercial instruments for the rapid testing of iron and steel for permeability. The Thompson permeameter employs the tractive force exerted between the pole of a magnetised bar and a piece of steel in direct contact with the pole. This force in dynes is $F = \mathfrak{B}^2 a/8\pi$, where $\mathfrak{B}$ = induction in bar in lines per square centimeter and $a$ = area of bar in square centimeters. Koepsel and Picout permeameters are induction-type instruments.

**309. S. P. Thompson's permeameter** is shown schematically in Fig. 117, where $AB$ is the test specimen in the form of a rod which passes through a hole in the top of a heavy yoke, $F$. The surfaces of the end of the rod and the yoke at $F$ are carefully machined. The force necessary to move the rod is measured with a spring balance at $S$. The induction is

$$\mathfrak{B} = 156.9\sqrt{\frac{P}{a}} + \mathfrak{H} \qquad \text{(gauses)} \qquad (40)$$

where $\mathfrak{B}$ = induction in lines per square centimeter (gauses) $P$ = pull in grams and $a$ = area in square centimeters.

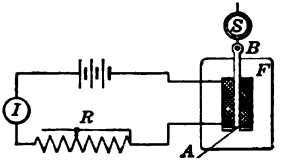

FIG. 117.—Thompson permeameter.

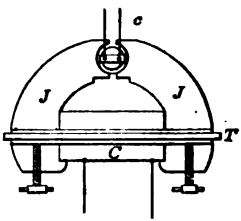

FIG. 118.—Koepsel permeameter.

**310. The Koepsel permeameter,** as made by Siemens Halske, is shown schematically in Fig. 118, where $JJ$ is a massive yoke divided at the centre so as to admit a moving coil $c$ to which a pointer is attached, the arrangement being similar to standard D'Arsonval-type direct-current instruments. This pointer moves over a scale graduated directly in lines per square centimeter. The magnetic circuit is completed through the test piece $T$, firmly clamped between the ends of the yoke in the usual manner. The value of $\mathfrak{B}$ corresponding to various magnetising currents in $C$ is indicated directly by the deflection with a known small current through $c$. Separate coils are placed on the yoke pieces, $JJ$, by means of which the reluctance of the various gaps is approximately compensated. But even with these coils, there is a flux leakage, so that correction or "shearing" curves have to be used. These curves, obtained by test with standardised specimens, are furnished with the instrument, as are also standardized test specimens with which the device can be checked from time to time.

Digitized by Google

**311. The principal advantages of traction permeameters** are their ruggedness and simplicity, which are important features in shop testing where rapidity is essential and only comparative data are required.

**312. The Picout permeameter** is a double-yoke, single-bar instrument in which the reluctance in the junction between test specimens and the rest of the magnetic circuit is compensated for. The scheme is indicated in Fig. 119, where $F_1$, $F_2$ are the two yokes. The square-bar test specimen $T$ is clamped between the ends of the yokes as shown. The two auxiliary magnetising coils on $F_1$, $F_2$ are first connected in such a manner that their magnetomotive forces are in series. There is then supposed to be no flux in the test bar, its magnetizing coil being out of circuit. The two coils on $F_1$, $F_2$ are then connected in opposition and the current in the test-bar coil adjusted until the flux in $F_1$, $F_2$ is the same as before, as indicated by a ballistic galvanometer or some other suitable method. The conditions in the test bar are then supposed to be the same as in a long, uniformly magnetised bar. The magnetomotive force of the test-bar coil simply overcomes the reluctance of the test bar and $\mathfrak{R}$ is calculated from the current and the constants of the coil as before, $\mathfrak{G}$ being measured with a test coil placed over the test bar.

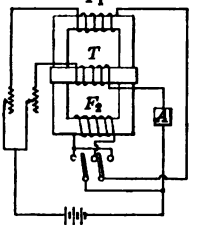

FIG. 119.—Picout permeameter.

**313. Hysteresis curves** are obtained by any of the methods described above, for permeability tests, in which a coil is used to measure the flux. In direct-indicating permeameters such as the Koepsel type, $\mathfrak{G}$ is noted for various values of $\mathfrak{R}$, first descending from a positive maximum value of $\mathfrak{R}$ to the negative maximum, and then ascending in the opposite direction.

**314. Ballistic step-by-step method of determining hysteresis.** Where high precision is desired the ballistic "step-by-step" method is used. This method is carried out as follows: The current in the magnetising circuit is adjusted to a value corresponding to maximum $\mathfrak{G}$. It is then reversed a few times to get the specimen in a cyclic state. By means of suitable switching arrangements, some resistance is suddenly cut into the circuit, thus reducing $\mathfrak{R}$ to a new value, which is carefully noted. The corresponding change in $\mathfrak{G}$ is determined with a ballistic galvanometer in the usual manner. This process is continued, step by step, until zero current is reached, when the circuit is reversed and the resistance cut out, step by step, until the same maximum value of $\mathfrak{R}$ is reached in the opposite direction. The whole process is then repeated and the other side of the loop obtained. In this method, the errors will be cumulative, but can be eliminated by going back each time to the original maximum $\mathfrak{R}$; furthermore, it is then a simple matter to insure that the conditions remain constant, by occasionally checking the value of $\mathfrak{G}$ corresponding to maximum $\mathfrak{R}$.

Knowing the value of $\mathfrak{G}$ at the start, the values corresponding to the various steps in the step-by-step method are obtained by adding algebraically the various changes in $\mathfrak{G}$ to this initial value. The resulting values of $\mathfrak{G}$ and $\mathfrak{R}$ suitably plotted on cross-section paper form the **hysteresis loop.**

**315. Hysteresis loss measurements.** The area of the hysteresis loop, measured in the units of the ordinates of the curve (by planimeter or otherwise) and divided by $4\pi$, gives the hysteresis loss in ergs per cubic centimeter per cycle, between flux densities $+\mathfrak{G}$ max. and $-\mathfrak{G}$ max. This method of measuring hysteresis loss is much too slow and expensive for commercial purposes, and several methods have been devised by means of which hysteresis losses can be measured directly, by electrical or mechanical means.

**316. Robinson's method of measuring hysteresis loss.** An example of an electrical method of measuring hysteresis loss is one used by L. T. Robinson.* It was designed primarily to reduce to a minimum the time and

* Robinson, L. T. "Commercial Testing of Sheet Iron for Hysteresis Loss." *Trans.* A. I. E. E., 1911, Vol. XXX, 741.

Digitized by Google

expense in preparing the sample, as well as the time spent in testing. Th specimen is a bundle of strips 0.5 in. (1.27 cm.) × 10 in. (25.4 cm.), weigh ing 1 lb. (0.45 kg.). It is placed in a simple straight solenoid, with a sens tive wattmeter (reflecting electrodynamometer) in series with the magneti ing coil. A separate winding is provided for the wattmeter potential coi thus simplifying the correction factor for wattmeter loss. The induction determined from the indication of a voltmeter, which is also connected to separate winding at the centre of the specimen. The flux which it indicate is much higher than that at the ends, but experiment has shown that th ratio of the maximum to the average is 1.3 to 1. Due allowance is therefor made, when adjusting the magnetizing current to such a value that th voltmeter deflection will correspond to the required average flux-density Measurements are made at 10 cycles, or less, in order to reduce the eddy current loss to a point where it can be eliminated by means of empiric corrections without serious error. The precision obtained is about ± per cent.

**317. In the Holden and the Ewing hysteresis meters, the loss i determined mechanically.** In the Holden meter the test specimen, ring of laminations about 1 cm. × 2 cm. (0.4×0.79 in.) cross-section, an 9 cm. (3.55 in.) diameter, is placed between the poles of a pair of revolvin magnets. The torque exerted on the specimen is resisted by a spiral spring The deflection of this spring which is necessary to bring the specimen bac to the zero position is a measure of the loss in ergs per cycle.

The **Ewing apparatus** is operated on a similar principle, except that th specimen is rotated instead of the magnets. The specimen is a bundle c strip ⅛ in. (1.6 cm.) square and 3 in. (7.6 cm.) long.

**318. Core-loss measurements.** The total loss in iron or steel sub jected to an alternating magnetic field is most accurately measured with wattmeter. In making precision measurements, the Hopkinson ring-specime can be used, but the Epstein apparatus is more convenient and has bee adopted by the American Society for Testing Materials.* Fig. 120 shows th scheme diagrammatically.

The specimen is arranged in the form of a rectangle. The magnetizin winding is divided into four solenoid each being wound on a form into whic one side of the rectangular specime is placed. The form is non-magnetic non-conducting and has the followin dimensions: inside cross-section, 4 cm (1.57 in.) × 4 cm.; thickness of wa not over 0.3 cm. (0.12 in.); windin length, 42 cm. (16.5 in.). Each lim of the specimen consists of 2.5 kg (5.5 lb.) of strips 3 cm. (1.18 in.) wid and 50 cm. (19.7 in.) long. Two o the bundles are made up of strips cut in the direction of rolling and two a right angles to the direction of rolling. The strips are held together wit tape wound tightly around the bundle. The bundles form butt joints a the corners with tough paper 0.01 cm. (0.004 in.) thick between. They ar held firmly in position by clamps placed at the corners.

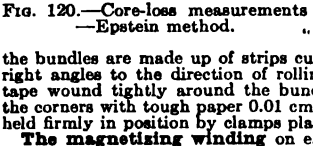

FIG. 120.—Core-loss measurements —Epstein method.

**The magnetizing winding** on each solenoid consists of 150 turns uni formly distributed over the 42 cm. (16.5 in.) winding-length, and has a resist ance of between 0.075 and 0.125 ohm. A secondary winding is uniformly wound underneath the first; it also contains 150 turns in each solenoid, an energises the potential circuit of the wattmeter and also the voltmeter wit which the induction is measured. The resistance should not exceed 0.2 ohm per solenoid. With a sine-wave e.m.f. impressed on the magnetizin winding, the maximum induction is

$$\mathfrak{B} = \frac{E\ 4\ lD\ 10^8}{4\ fN\ nM} \quad \text{(gausses)} \qquad (41$$

where $E$ = volts indicated by voltmeter, $l$ = length of specimen, $D$ = specific gravity (7.5 for alloy or high-resistance steels and 7.7 for standard or low-

* Standard Magnetic Tests of Iron and Steel; *Trans.* A. S. T. M., 1911 Vol. XI; p. 110.

Digitized by Google

resistance steels), $f$ = form factor of magnetizing electromotive force (1.11 for sine-wave), $N$ = total secondary turns, $n$ = cycles per second, and $M$ = total mass in grams. The wattmeter gives the total loss in the iron, plus that in the secondary circuit. The latter is calculated from the resistance and the voltage, and deducted from the wattmeter reading.

**319. For comparative commercial measurements of core losses,** a single simple solenoid may be used.* The wattmeter indications are standardized with a standard sample. The accuracy obtained is quite sufficient for most factory purposes.

**320. Separation of eddy-current and hysteresis losses** in the core is usually accomplished by taking advantage of the fact that with a given value of $B_{max}$, the hysteresis loss varies directly with the frequency and the eddy-current loss with square of the frequency. The specimen is arranged as in a core-loss test and the loss noted at two frequencies, the induction being kept the same in the two cases. By means of two simultaneous equations, with two unknown quantities, both losses can be calculated.

**321. Precautions in magnetic testing.** Where the induction is measured by means of a stationary test coil surrounding the specimen, the space between the coil and the test specimen should be as small as possible. This can ordinarily be made so small that the leakage error is negligible.

Before induction measurements are made, the specimen should be carefully demagnetized. This is best done by first magnetizing to a value well above the maximum at which measurements will be made; the current is then gradually reduced to zero, being rapidly reversed meanwhile. Alternating current of 25-cycle frequency is convenient where much work is to be done.†

In loss measurements, the temperature of the specimen should be carefully noted, because this affects the eddy-current loss. The exciting winding should therefore be sufficiently large to avoid heating of the specimen. In precision work, the apparatus is placed in an oil bath.

In tests of sheet materials, the strips should not be too narrow, because of the hardening at the edges due to cutting. This effect is negligible with a width of 2 in. (5 cm.). Care should be taken that burrs are removed from the edges and that the only insulation between sheets is the natural scale or oxide. The test specimen should be composed of strips cut from the sheets in both directions.

The readings of a **ballistic galvanometer** should be kept at about the same magnitude by varying the resistance in series with it. The observational error is thus kept about constant.

## MECHANICAL POWER MEASUREMENTS

BY F. MALCOLM FARMER, M.E.

### TORQUE MEASUREMENTS

**323. Torque is best measured with dynamometers,** of which there are two classes, absorption and transmission.* Absorption dynamometers absorb the total power delivered by the machine being tested, while transmission dynamometers absorb only that part represented by friction in the dynamometer itself.

**324. The Prony brake** is the most common type of **absorption dynamometer.** It is simply a brake applied to the surface of a pulley on the shaft of the machine being tested, together with suitable means for vary-

* Carpenter and Diedrichs. "Experimental Engineering" (Wiley Sons, 1912). J. A. Moyer. "Power Plant Testing" (McGraw-Hill Book Co. Inc., 1913).

Digitized by Google

ing the friction produced. The torque developed by the machine to overcome the friction is determined from the force required to prevent rotation of the brake.

**325. The principal forms of Prony brakes** are shown schematically in Figs. 121, 122, 123 and 124. In Fig. 121 the load is applied by tightening

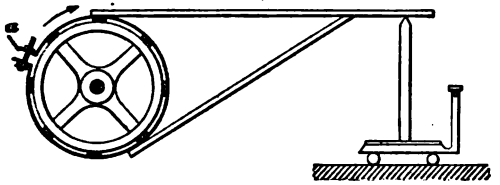

FIG. 121.—Prony brake.

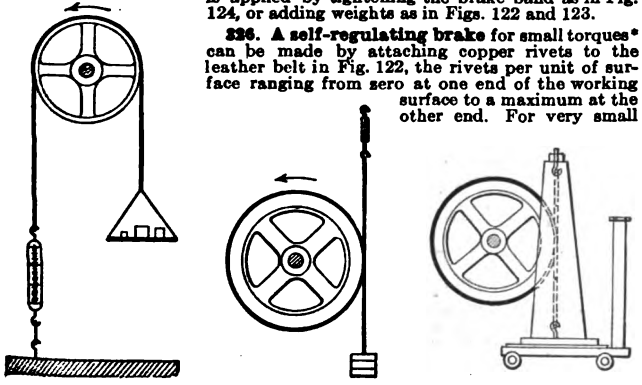
the brake band at $a$, and the corresponding torque is measured by noting the force required at the end of a lever-arm of known length in order to prevent rotation. This force is usually measured with ordinary weighing scales or a spring balance. In Figs. 122, 123 and 124, the brake band is a belt or rope applied directly to the surface of the pulley, and the force is measured at the pulley surface by the various methods indicated. The load is applied by tightening the brake band as in Fig. 124, or adding weights as in Figs. 122 and 123.

**326. A self-regulating brake** for small torques* can be made by attaching copper rivets to the leather belt in Fig. 122, the rivets per unit of surface ranging from zero at one end of the working surface to a maximum at the other end. For very small



FIGS. 122, 123, and 124.—Prony brake.

torques a round belt in a grooved pulley and with small steel wire wound spirally around it, zero turns per inch at one end to maximum turns at the other, makes a simple and very satisfactory brake.

**327. Formulas for calculation of torque from dynamometer measurements.** The torque, $T$, in the various forms of Prony brakes (Par. 324) is determined as follows: In Fig. 121, $T = F_p L$, where $F_p$ = force measured at end of brake-arm, $L$ = length of brake-arm or distance from centre of shaft to point at which the force is measured. In Figs. 122 and 123, $T = (F_w - F_p)L$, where $F_w$ = weight attached to end of brake-band, $F_p$ = reading of spring balance, $L$ = brake-arm = radius of pulley plus one-half the thickness of belt or rope. In Fig. 124, $T = F_p L$, where $F_p$ = force weighed on scales, $L$ = brake-arm = radius of pulley plus one-half the thickness of belt or

*H. M. Scheibe. "A Self-regulating Brake." *Electric Journal*, 1907, Vol. IV, p. 118.

Digitized by Google

rope. If $F$ and $L$ are measured in pounds and feet respectively, $T$ will in lb. ft.

**328. Dissipation of heat in friction brakes.** The energy dissipated the brake appears in the form of heat. In small brakes natural cooling sufficient, but in large brakes special provisions have to be made to dissipa the heat. Water-cooling is the most common method, one scheme e ploying a flanged pulley. About 100 sq. in. of rubbing surface of bra should be allowed with air cooling, or about 50 sq. in. with water cooli per horse-power.

**329. For very large torques, other forms of absorption brakes a used.** In the **Alden brake**, a rotating cast-iron disc rubs against th copper discs which are held stationary. The friction is adjusted by varyi the pressure of the cooling water in the chamber surrounding the copp discs. The tendency of the copper disc member to rotate is measured wi a lever as in the Prony brake.

The **Westinghouse turbine brake** employs the principle of the wat turbine and is capable of absorbing several thousand horse-power at ve high speeds.

In the **magnetic brake**, a metallic disc on the shaft of the machine bei tested is rotated between the poles of magnets mounted on a yoke which free to move. The pull due to the eddy currents induced in the discs is mea ured in the usual manner by counteracting the tendency of the yoke revolve.

**330. The principal forms of transmission dynamometers** are t lever, the torsion and the cradle types. An example of the **lever type**

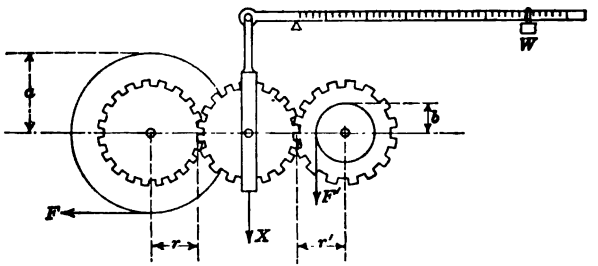


FIG. 125.—Transmission dynamometer.

shown in Fig. 125, where $F$ is the force applied to the dynamometer, an $F'$ is the force being delivered. When the downward force, $X$, is balance by the weight $W$, the following formula holds,

$$F = \frac{1/2(1+\mu)Xr}{a} \qquad (42$$

where $\mu$ = coefficient of friction determined experimentally.

**331. In torsion dynamometers**, the deflection of a shaft or spiral spring which mechanically connects the driving and driven machines, is used t measure the torque. The spring or shaft can be calibrated statically b noting the angular twist corresponding to a known weight at the end of known lever-arm perpendicular to the axis. When in use the angle can b measured by various electrical and optical methods. In one method th angular displacement between two points on the shaft is determined by mean of two discs of insulating material, in the periphery of each of which is se a very thin piece of metal. The two pieces of metal are connected electric ally through the shaft. A light, thin metal brush rests on the peripher of each disc, and the two brushes are connected together through a batter and an indicator such as a bell, or a telephone. At no load, one brush i moved until the electrical circuit is completed once every revolution. Th angle through which either brush has to be moved as the load is increased, i order to keep the circuit closed, is then measured.

Digitized by Google

**332. The cradle dynamometer** is a convenient and accurate device which is extensively used for routine measurements of the order of 100 h.p. or less. An electric generator is mounted on a "cradle" supported on trunnions and mechanically connected to the machine being tested. The pull exerted between the armature and field tends to rotate the field. This torque is counterbalanced and measured with weights moved along an arm in the usual manner.

## SPEED MEASUREMENTS

**333. Revolutions are measured** with speed counters and tachometers. **Speed or revolution counters** are attached directly to the shaft to be measured and record the total revolutions from the instant that the mechanism is connected. They usually consist of an arrangement of worm and gears, the total revolutions being shown by a graduated dial moving under a pointer, or by a cyclometer dial on which the total revolutions are indicated numerically at each revolution. In order to obtain the speed, the intervening time must be observed simultaneously.

**334. Tachometers or speed indicators** indicate the speed directly and thus include the time element. The principal types are centrifugal, liquid, reed and electrical. In the centrifugal type, a revolving weight on the end of a lever moves under the action of centrifugal force in proportion to the speed, as in a fly-ball governor. This movement is indicated by a pointer which moves over a graduated scale. In the portable or hand-type, the tachometer shaft is held in contact with the end of the shaft being measured, and in the stationary type, the instrument is either geared or belted. In the liquid tachometer of the Veeder type, a small centrifugal pump is driven by a belt consisting of a light cord or string. This pump discharges a colored liquid into a vertical tube, the height of the column being a measure of the speed.

**Reed tachometers** are similar to reed-type frequency indicators (Par. 279), the reeds being set in resonant vibration corresponding to the speed of the machine, by various means. The instrument may be set on the bedframe of the machine where any slight vibration due to the unbalancing of the reciprocating or revolving member will set the corresponding reed in vibration. Some forms are belted to the revolving shaft and the vibrations imparted by a mechanical device. **Electrical tachometers** may be either reed instruments operated electrically from small alternators geared or belted to the machine being measured, or ordinary voltmeters connected to small permanent-magnet, direct-current generators driven by the machine being tested.

**335. Chronographs** are speed-recording instruments in which a graphical record of speed is made. In the usual forms, the record-paper is placed on the surface of a drum which is driven at a certain definite and exact speed by clock-work or weights, combined with a speed-control device so that 1 in. on the paper represents a definite time. The pens which make the record are attached to the armatures of electromagnets. With the pens in contact with the paper and making a straight line, an impulse of current causes the pen to make a slight lateral motion and therefore a sharp indication in the record. This impulse can be sent automatically by a suitable contact-mechanism on the shaft of the machine or by a key operated by hand. The time per revolution is then determined directly from the distance between marks.

# THERMOMETRY, PYROMETRY AND HEAT CONDUCTIVITY

**BY G. K. BURGESS, SC.D.**
**AND**
**PAUL D. FOOTE, A.M.**

## THERMOMETRY

**336. Temperature scale.** The standard scale of temperature from 100 deg. cent. to −35 deg. cent. is based on the hydrogen gas thermometer. Below −35 deg. cent. the scale is usually referred to the helium or hydrogen thermometer while in the range 100 to 1,600 deg. cent. the nitrogen thermometer is used. Still higher temperatures are based on the **Wien-Planck** or **Stefan-Boltzmann radiation laws.** Ultimately measurements of

Digitized by Google

temperature should be expressed in some one standard scale such as the thermodynamic or ideal gas scale. The hydrogen and nitrogen gas thermometers differ from this scale by various small amounts. The scale defined by the **radiation laws** is the thermodynamic scale, assuming these laws to have a sound theoretical basis. For the past 25 years it has been possible to express temperatures to 0.002 deg. cent. in the range 0 to 100 deg. cent., but outside of this interval the accuracy is far from being what is desired. Only recently for example, has the certainty of the sulfur boiling-point been closer than 0.5 deg. and of the gold melting-point 5 deg. cent. At the present time the International Bureau and the several national laboratories are interchanging communications with the object of establishing an international temperature scale.

**337. Mercurial thermometers.** Primary mercury thermometers are constructed of the very best thermometric glasses such as verre dur, Jena $16^{111}$, Jena $59^{111}$, and the scales defined by the differential expansion of these glasses and the mercury have been compared with the gas thermometer so that their corrections are fairly well established. (See Circular No. 8 of the Bureau of Standards.)

**338. Laboratory and industrial mercury-in-glass thermometers (range − 35 to + 560 deg. cent.) are calibrated** by direct comparison with standards. Two points which frequently occasion trouble in the use of mercury thermometers are (a) **correction for emergent stem**, (b) correction for **thermometric lag.**

**339. Correction for emergent stem.** In general the calibration corrections are determined for total immersion of the thermometer. When used with the stem emergent into space either hotter or colder than the temperature of the bulb, a stem correction must be applied to the observed reading of the thermometer in addition to the calibration correction. This stem-correction may amount to more than 20 deg. cent. for measurements made with a mercurial thermometer at 400 deg. cent. (750 deg. fahr.). The stem correction may be computed from the formula: Stem Correction = $K \times n(T^\circ - t^\circ)$ where $K$ = factor for relative expansion of mercury in glass; 0.00015 to 0.00016 for centigrade thermometers, 0.000083 to 0.000089 for fahrenheit thermometers; $n$ = number of degrees emergent from the bath; $T$ = temperature of bath; $t$ = mean temperature of emergent stem.

**Example:** Suppose that the observed temperature was 100 deg. cent. and the thermometer was immersed to the 20-deg. mark on the scale, so that 80 deg. of the mercury column projected out into the air, and the mean temperature of the emergent column was found to be 25 deg. cent.; then—stem cor. $= 0.00015 \times 80 \times (100 - 25) = 0.9$ deg. cent. As the stem was at a lower temperature than the bulb, the thermometer read too low, so that this correction must be added making the correct temp. = 100.9 deg. cent. The mean temperature of the emergent stem may be approximately measured by a small auxiliary thermometer, by a Faden thermometer, or by surrounding the stem with a water jacket and observing the temperature of this bath.

**340. Correction for thermometric lag** (Bur. of Standards, Reprint No. 171). When a thermometer is immersed in any medium it does not take up the temperature of the medium immediately, but approaches it asymptotically. This effect may be minimised by stirring the bath. With vigorous stirring in the case of a liquid bath, the thermometer reading should be correct to within 1 per cent. of the original difference in temperature of the thermometer and bath after 10 to 60 sec. exposure. In absolutely quiet air this degree of accuracy might require 20 min. Fanning the thermometer might reduce the time to 1 min. With caution, corrections for lag may be neglected in ordinary laboratory work.

**341. High-temperature thermometers.** Although mercury boils at 357 deg. cent. under atmospheric pressure, by filling the space above the mercury with $CO_2$ or $N_2$ under sufficient pressure, certain mercury-in-glass thermometers may be used at a maximum temperature of about 560 deg. cent. Glasses used are Jena $16^{111}$ to 450 deg. cent., Jena $59^{111}$ to 520 deg. cent., and special grades of combustion tubing to 560 deg. cent. Care must be exercised that the thermometer is not overheated. If the long portion of the stem is cold, the stem correction may amount to 40 deg. cent. and hence while the mercury stood at 500 deg. cent. the true temperature of the bulb would be 540 deg. cent. A few moments at that tempera-

Digitized by Google

ture might change the ice point 20 deg. cent. in the case of Jena 59$^{111}$ or any mercury-in-glass thermometer except one constructed of high-grade combustion tubing.

**342. Low-temperature thermometers.** For the measurement of temperatures below the range of the mercury thermometer (− 35 deg. cent.), there are available alcohol (−70 deg. cent.), toluene (−90 deg. cent.), and petroleum-ether or pentane (−200 deg. cent.) liquid-in-glass thermometers, copper-constantan and other thermocouples, and electric resistance thermometers. With these types of liquid-in-glass thermometers the same precautions apply as with mercury, and in addition special care must be taken to prevent the liquid from sticking to the sides of the glass. On account of viscosity of the liquid at low temperatures the thermometer must be slowly cooled to the temperature of the bath, cooling first the bulb and then the stem.

**343. Calorimetric mercury thermometers** are of two types, the ordinary mercury thermometer with a total stem length of 10 to 15 deg. cent., graduated in 0.05-deg. to 0.02-deg. intervals, and the **Beckmann thermometer** arranged so that part of the mercury may be removed from the bulb in order to utilize the short scale (5 or 6 deg. cent. graduated in 0.01-deg. intervals) for differential work at various temperatures. In addition to the stem corrections the Beckmann type requires a setting correction depending upon the amount of mercury remaining in the bulb. Calorimetric thermometers may be in error by 1 per cent. of the indicated temperature scale differences, and consequently should be calibrated. The highest accuracy attainable is from 0.5 to 0.1 per cent. For greater precision, thermocouples or resistance thermometers are available.

**344. Annealing of thermometers.** Every thermometer, particularly if intended for use above 100 deg. cent., should undergo suitable annealing. Thorough annealing requires from 4 to 10 days at a temperature of 450 deg. cent. or as much higher as the glass will safely stand, and the annealing may well be followed by a period of slow cooling extending over several days. Alternate heating and cooling is also beneficial.

## PYROMETRY

**345. Thermoelectric pyrometry.** In pyrometers of this type temperatures are measured by the magnitude of the electromotive forces set up between wires of different materials when one junction is exposed to the temperature to be measured and the other junction (or junctions) is kept at some known temperature.

**346. Material of Couple.** The **LeChatelier couple** (Pt, 90Pt–10Rh) is in general the most satisfactory couple in the range 300 to 1,500 deg. cent., although (Pt, 90Pt–10Ir) is frequently used. For temperatures below 1,000 deg. cent. (Cu, 60Cu−40Ni), (Ni−Cu), (Ni, 90Ni−10Cr), and other alloys serve satisfactorily in technical work. From 500 deg. cent. to the lowest temperatures, copper-constantan and iron-constantan are materials frequently used. At 1,000 deg. cent. (cold junction = 0 deg. cent.) the LeChatelier couple develops an e.m.f. of 9.5 millivolts. Many base-metal couples will develop an e.m.f. of several times this magnitude.

**347. Formulas and calibration.** (Pt, Pt−Rh) and (Pt, Pt−Ir) couples have a temperature-e.m.f. relation of the form

$$e = a + bt + ct^2 \tag{43}$$

from 300 to 1,200 deg. cent.; and

$$e = pt + qt^2 \tag{44}$$

from 0 to 100 deg. cent., where $t$ is the temperature centigrade and $a$, $b$, $c$, $p$, $q$, are empirical constants. Three calibration points serve to determine $a$, $b$, $c$. Those most satisfactory are the melting- or freezing-points of zinc or lead, antimony (Kahlbaum) or aluminum, and copper. Ordinary base-metal couples may have transition points in the temperature-e.m.f. curve, so that in general a calibration must be made at a larger number of temperatures, when the best curve may be drawn through the plotted points.

**348. Galvanometers** used to measure the e.m.f. developed by a couple should preferably have a resistance high in comparison with that of the couple. The relation between the true e.m.f. of the couple $E$ and that indicated by a galvanometer $E'$ is

Digitized by Google

$$E = \frac{E'(R+r+r')}{R} \tag{45}$$

where $R$, $r$, $r'$ are the resistances of the galvanometer, thermocouple and leads respectively.

**349. Cold-junction corrections.** If a thermocouple is calibrated with cold junctions at 0 deg. cent. and used with cold junctions at $t_0$ deg. cent. one must add to the e.m.f. actually developed, the value of the e.m.f. developed when the hot junction is at $t_0$ deg. cent. and the cold junctions are 0 deg cent., to obtain the correct value of the e.m.f. corresponding to temperatures shown by the calibration. If the indicator is graduated to read temperature directly, instead of e.m.f., the cold-junction correction has the form $p$ deg. cent. = Factor $\times t_0$. For the LeChatelier couple this factor is about 0.6 in the range 300 to 700 deg. cent. and 0.5 from 700 to 1,400 deg. cent. Base-metal couples show factors varying from 0.2 to 1.2 depending upon the particular alloy used.

As an example, suppose the indicated temperature (cold junction = 40 deg. cent.; calibration temperature = 0 deg. cent.) by the LeChatelier couple is 1,000 deg. cent. Then $p = 0.5 \times 40 = 20$ deg. True temp. = 1,000 + 20 = 1,020 deg. cent.

**350. Certain precautions** should be taken in the use of **thermocouples.** The hot junction is usually formed by welding the dissimilar metals in an oxyhydrogen flame. Other junctions may be soldered or thoroughly secured with binding screws. The entire couple should be annealed at as high a temperature as it will safely stand in order to render it as homogeneous as possible. The couple must be protected from furnace vapors or direct contact with liquid baths, and the two leads must be insulated from each other.

**351. Electrical resistance pyrometry.** This method of high-temperature measurement ordinarily makes use of the variation in the electrical resistance of platinum and is capable of great sensibility. In one of its simplest forms the pyrometer consists of a coil of platinum wire wound on mica, and encased in a protecting tube of porcelain. On account of the distillation of platinum, high-resistance coils of small wire are not used much above 900 deg. cent. However, coils constructed of 0.6-mm. wire may serve satisfactorily to 1,200 deg. cent.

**352. Three-lead type—Wheatstone bridge method.** For the purpose of eliminating the resistance of the leads to the coil, a third wire is

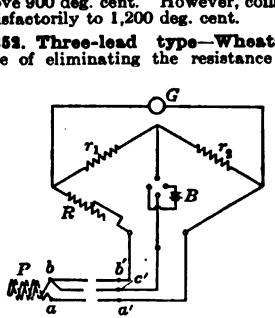

FIG. 126.—Three-lead resistance thermometer.

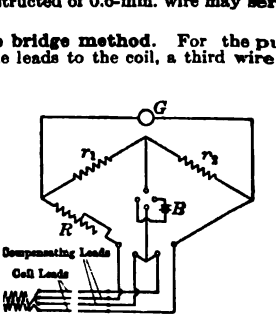

FIG. 127.—Four-lead resistance thermometer.

frequently introduced as in Fig. 126. The coil $P$ forms one arm of a dial-type bridge, of which the others are $r_1$, $r_2$ and $R$, whence from the principle of the bridge, if the galvanometer $G$ remains undeflected,

$$P = \frac{r_2(R+bb')}{r_1} - aa' \tag{46}$$

$r_2$ is usually made equal to $r_1$ and $bb'$ is constructed as nearly as possible identical with $aa'$, so under these circumstances $P = R$ regardless of the tem-

Digitized by Google

perature or resistance of the leads. This type of thermometer may also be used with a differential galvanometer.

**353. Four-lead type—Wheatstone bridge method.** The compensating leads are inserted in one arm of the bridge $R$ and the thermometer leads in the other, as shown in Fig. 127. This type may be used with a slide-wire bridge.

**354. Four-lead potential-terminal type** (Fig. 128). The resistance of the coil is measured by sending the same current from a storage battery through the thermometer and a known resistance in series, and measuring the potential drop by means of a potentiometer, first across the known resistance and then across the thermometer coil. Two of the thermometer terminals are current leads and two are potential leads. The current ordinarily used is of the magnitude 0.003 to 0.05 amp., and should be the same as that used during the calibration of the instrument, to eliminate the errors due to the heating effect of this current.

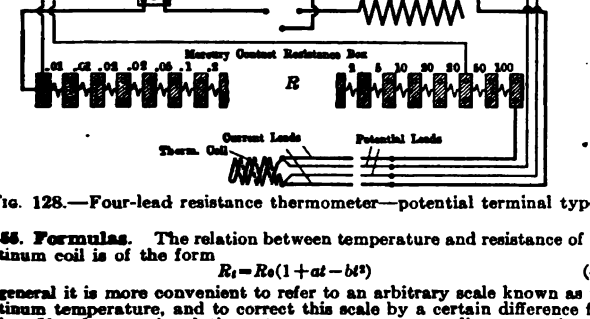

FIG. 128.—Four-lead resistance thermometer—potential terminal type.

**355. Formulas.** The relation between temperature and resistance of the platinum coil is of the form

$$R_t = R_0(1 + at - bt^2) \tag{47}$$

In general it is more convenient to refer to an arbitrary scale known as the platinum temperature, and to correct this scale by a certain difference formula. If $pt$ denotes the platinum temperature corresponding to a resistance $R$, we have the relation

$$pt = \frac{100(R - R_0)}{R_{100} - R_0} \tag{48}$$

where $R_{100}$ and $R_0$ are the resistances at 100 deg. cent. and 0 deg. cent. respectively. The relation between the centigrade temperature $t$ and the platinum temperature $pt$ is as follows:

$$t - pt = \frac{\delta\left(\frac{t}{100} - 1\right)}{100} \cdot t \tag{49}$$

**356. Calibration.** For the calibration of a thermometer, the coil of which is of the highest purity platinum, resistance measurements are made at three temperatures, as follows: the ice point, the steam point and the boiling point of sulphur. Substituting the values thus obtained in formula for $pt$ (Par. 355) the value of $pt$ corresponding to the sulphur point is known. Referring to the formula for $t$ (Par. 355), the value of $\delta$ should be found a constant of the magnitude 1.49 ± 0.01, whence from the two formulas a table of $R$ and $t$ may be computed. Such a calibration will indicate temperatures in the range −50 to 1,200 deg. cent. as closely as they are known in terms of the gas scale. If $\delta$ is found considerably greater than 1.49 due to impurity of the platinum, there is advantage in using a fourth calibration point, such as the silver freezing-point as a check.

**357. Adaptability.** The **resistance thermometer** is especially adapted to the measurement of small temperature changes such as occur in calor-

Digitized by Google

imetry, to the determination of freezing-points, etc., and to special physica and thermochemical investigations where an accuracy of one or two part in 10,000 may be attained (see Bur. of Standards, Reprint No. 68 and No 124). In the technical industries this type of thermometer with one of th many forms of indicators available is highly satisfactory.

**358. Radiation.** The temperature of bodies may be estimated from th radiant energy which they send out in the form of visible light or of the longe infra-red rays which may be detected by their thermal effects. Since th intensity of radiation increases very rapidly with a rise in temperature, i would appear that a system of pyrometry based on the intensity of the ligh or total radiation from a hot body would be an ideal and simple one. How ever, different substances at the same temperature show vastly differen intensities at a given wave length, or in other words, the **absorbing or emis sive powers** may vary with the substance, with the wave length, and als with the temperature.

**359. Black-body radiation.** A substance which absorbs all the radia tion of any wave length falling upon it is known as a **black body.** Such a body will emit the maximum intensity of radiation for any given temperatur and wave length. No such material exists, but a very close approximatio is obtained by heating the walls of a hollow opaque enclosure as uniformly a possible and observing the radiation coming from the inside through a very small opening in the wall.

**360. Stefan-Boltzmann law.** The relation between the total energy radiated by a black body and its temperature is expressed by the equatio $J = \sigma(T^4 - T_0^4)$, where $J$ is the energy of all wave lengths emitted per squar centimeter of surface, $T$ and $T_0$ the absolute temperatures of the radiato and receiver respectively, and $\sigma$ a constant of about the value $5.8 \times 10^{-12}$ watt cm.$^{-2}$ deg.$^{-4}$. In general $T_0^4$ is negligible in comparison with $T^4$ so that th above relation becomes $J = \sigma T^4$. Although the total energy emitted by an substance is not that emitted by a black body at the same temperature, it may be considered as some fractional part of that from the ideal radiator, thi fraction $\epsilon$ being known as the total emissivity. If $S$ denotes the apparen absolute temperature, *i.e.*, the temperature on the black-body scale corre sponding to an amount of energy equivalent to that emitted by the non black substance at a true temperature $T$ deg. absolute, the relation betwee its total emissivity $\epsilon$ and the quantities $S$ and $T$ is:

$$\text{Log } \epsilon = 4(\log S - \log T) \qquad (50)$$

**361. Radiation pyrometry.** The quantity of heat a body receives by radiation from another body depends upon certain conditions relative t each of the two bodies, namely (a) temperature, (b) area of surface, (c) dis tance apart, (d) emissive and absorbing powers. A pyrometer may be s constructed that conditions (b) and (c) compensate one another, at leas within certain prescribed limits, so that for all technical purposes the radia tion received by the instrument depends only upon the temperature of th radiating source and its emissivity. The pyrometer is calibrated by sighting upon a black body, the temperature of which may be obtained by thermo couples. Specially constructed furnaces for this purpose are available in al testing laboratories.

**362. Féry mirror telescope pyrometer.** (Fig. 129.) Radiation of al wave lengths is brought to a focus by means of a concave gold mirror $M$ upo the hot junction of a minute thermocouple located at $T$. The cold junctions of the couple are suitably screened from the direct radiation of the hot body. The concentration of heat at the hot junction develops an e.m.f. which may be measured by a potentiometer or galvanometer. In practice the galvanometer is usually calibrated to read temperature directly. The relation between the e.m.f. and the temperature may be expressed by the equation $E = aT^b$, or in log form, $\log E = k + b \log T$, where $T$ is the absolute tempera-

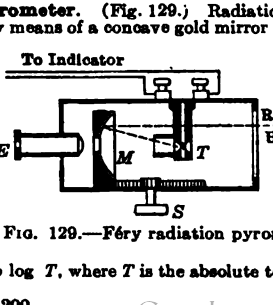

FIG. 129.—Féry radiation pyrometer.

Digitized by Google

ture and $a$ or $k$ and $b$ are empirical constants. In general $b$ approximates the value 4, but may have a range varying from 3.5 to 4.5 depending upon the construction of the individual instrument. The pyrometer should be sharply focused upon the radiating source and for this purpose an ingenious device is mounted in the instrument by means of which straight lines appear broken until the mirror is adjusted by the thumb screw $S$ to the proper position. Foster has transformed the Féry telescope into a fixed-focus pyrometer by placing the thermocouple and a small front diaphragm at the conjugate foci of the gold mirror.

**363. Thwing pyrometer.** In the Thwing pyrometer the reflecting mirror is replaced by an aluminum cone which by multiple reflections concentrates the radiation at its apex on one or more small thermocouples in series with a portable galvanometer. The instrument requires no focusing, the front diaphragm acting as a source. The object sighted upon must be large enough to cover the projection of the cone through this diaphragm.

**364. Precautions in the use of radiation pyrometers.** The mirrors or reflecting devices must be kept bright and free from dust. In the case of the Féry pyrometer, errors amounting to 100 deg. cent. have been observed, due to ordinary accumulation of dirt upon the large gold mirror.

Many radiation instruments require several minutes of exposure to the radiating source to indicate a maximum reading due to the slow heating of the hot junction, while others require less than 20 sec. The maximum indication should be accepted. Care must be taken that the source is large enough to completely "fill" the aperture of the pyrometer. It is usually impossible to focus upon the back of a furnace through a very small peephole and obtain reliable results; in such cases the hole must be enlarged so that it does not cut into the cone of rays entering the instrument, or the pyrometer may be focused upon the hole itself. In the latter case the hole must be large enough to cover the thermocouple in the Féry pyrometer or the front diaphragms of the Thwing and Foster pyrometers. Variations in room temperature in general affect the hot and cold junctions nearly alike, so that very little error is introduced in the reading of a radiation instrument from this cause.

**365. Emissivity corrections for radiation pyrometers.** In the case of sighting upon peep-holes in furnaces, kilns, etc., the total-radiation pyrometers indicate approximately true temperatures. When sighting upon objects in the open, certain corrections must be applied. These corrections are but roughly known. The following table (Par. **366**) shows the true temperatures corresponding to the pyrometer indications when sighting upon molten iron ($\epsilon = 0.28$), molten copper (0.15), copper oxide (0.60), iron oxide (0.86), and nickel oxide. The data is obtained from the work of Thwing, Burgess and several experiments of the authors.

**366. Total Emissivity Corrections**

| Observed temperature, deg. cent. | True temperature, deg. cent. | | | | |
|---|---|---|---|---|---|
| | Molten iron | Molten copper | Copper oxide | Iron oxide | Nickel oxide |
| 600 | ..... | 1,130 | 720 | 630 | 710 |
| 700 | ..... | 1,290 | 830 | 735 | 800 |
| 800 | 1,200 | ..... | 945 | 840 | 895 |
| 900 | 1,340 | ..... | 1,060 | 945 | 985 |
| 1,000 | 1,475 | ..... | 1,170 | 1,050 | 1,075 |
| 1,100 | 1,610 | ..... | ..... | 1,155 | 1,165 |
| 1,200 | 1,750 | ..... | ..... | 1,260 | 1,255 |

**367. Wien's law.** Wien's laws relate to the distribution of the energy of the black body in the spectrum. The law chiefly concerned in optical pyrometry expresses the relative intensity of the energy emitted at any given wave length $\lambda$ and temperature in the following manner:

$$I = c_1 \lambda^{-5} e^{-\left(\frac{c_2}{\lambda T}\right)} \qquad (51)$$

Digitized by Google

where $I$ is the energy corresponding to the wave length $\lambda$ and the absolute temperature $T$ of the radiator, $e$ the base of the natural (Napierian) system of logarithms, and $c_1$ and $c_2$ empirical constants. $c_2$ may be taken as 14,500 when $\lambda$ is measured in microns, *i.e.*, $\mu$ (Sec. 1). $c_1$ depends upon the energy units. If $S_\lambda$ is the apparent absolute temperature corresponding to the wave length $\lambda$ of a non-black body at a true absolute temperature $T$, it follows that

$$\frac{1}{T} - \frac{1}{S_\lambda} = \left(\frac{\lambda}{c_2 \log e}\right) \log A_\lambda \qquad (52)$$

where $A_\lambda$ is the absorptivity = emissivity = unity minus reflecting power of the radiator at the particular wave length $\lambda$ and temperature $T$.

**368. Optical pyrometry.** Optical pyrometers are based upon the photometric principle of matching the intensity of visible monochromatic radiation emitted by a substance, with that of the same wave length or color from a standard reproducible source such as the amylacetate lamp, or a constant source such as an electric lamp. The instruments are calibrated by comparison with the intensity of radiation from a black body, the primary standard to which all measurements are referred.

**369. Féry absorption pyrometer.** (Fig. 130.) The apparatus consists essentially of a telescope carrying a small oil or gasoline lamp $L$. The image of the flame of this lamp is projected on a silver strip at $M$ adjusted to the focal point of the ocular and objective system. By means of the black-glass absorbing wedges $w$, $w$, the intensity from the source may be varied until a match of the photometric field (see small Fig.) is obtained. A red-glass screen is used in the ocular so that fairly monochromatic light of this color (0.65 or 0.63$\mu$) is compared. The relation between the thickness of the wedges $x$, read on a scale, and the absolute temperature $T$ is $x + P = Q/T$, where $P$ and $Q$ are constants determinable by two calibration points. The instrument must be focused upon the radiating source but no corrections for distance need be applied. The **LeChatelier** pyrometer, the first optical pyrometer developed, is similar in principle but is not of constant aperture and important corrections must be made with change of focus. The **Shore** pyroscope has a direct-reading temperature scale controlled by a diaphragm before the standard oil lamp. In all of these instruments the purity of the gasoline, oil, or even the amylacetate used in the comparison lamps is of little importance. Considerable impurity may be introduced without affecting the calibration perceptibly.

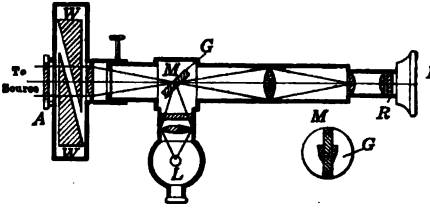

FIG. 130.—Féry optical pyrometer.

**370. Wanner pyrometer.** (Fig. 131.) The comparison light is a six-volt incandescent lamp illuminating a glass matt surface; monochromatic red light is produced by means of a direct-vision spectroscope $P$ and a screen cutting out all but a narrow band in the red ($\lambda = 0.656\mu$) and the photometric comparison is made by adjusting to equal brightness both halves of the photometric field by means of a polarising arrangement. The slit $S_2$ is illuminated by the incandescent lamp while light from the furnace enters $S_1$. After passing through a Rochon prism and a biprism, the light from the two slits polarized in planes at 90 deg. to each other reaches the Nicol prism $N$. Rotation of this analyzer serves to extinguish one field and brighten the other simultaneously, until a match is effected. A reference angle is chosen, usually about 30 deg., corresponding to the apparent temperature of a section of an amylacetate flame. The instrument is set at this normal point and sighted upon the ground-glass screen of the flame gage. The

Digitized by Google

brightness of the electric lamp is then varied by altering the current through it until the halves of the photometric field are matched. Maintaining this current constant, the pyrometer is ready for calibration or for temperature measurements. The instrument follows the law

$$\log\text{-}\tan\varphi = a + \frac{b}{T} \tag{53}$$

where $\varphi$ is the angular reading of the analyzer, $T$ the absolute temperature and $a$ and $b$ empirical constants. The relation between log-tan $\varphi$ and $1/T$ is linear. Two calibration points serve to determine $a$ and $b$, when a table or plot may be made of $\varphi$ vs. $t$ deg. cent. ($T-273$). Frequent adjustments should be made of the current through the electric lamp necessary to obtain a match at the normal point when sighted on the amylacetate lamp. The electric lamp burns at a high temperature (about 1,800 deg. cent.) and consequently deteriorates rapidly. For the highest accuracy this adjustment should be made before and after a series of temperature readings; in industrial plants once a day or once a week will answer depending upon the amount of use.

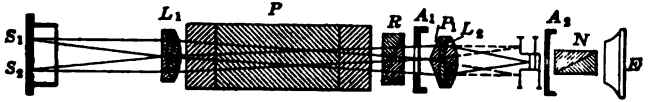

FIG. 131.—Wanner pyrometer.

**371. The Scimatco pyrometer** is an improved form of the Wanner (Par. 370). The delicate optical parts are encased in a strong metal sheath, and the addition is made of a direct-reading temperature scale, besides many adjustments for convenience of operation.

**372. Morse and Holborn-Kurlbaum pyrometers.** The filament of a small electric lamp is placed at the focal point of an objective and ocular forming an ordinary telescope, which superposes the image of the furnace upon the lamp. The tip of the filament is brought to a photometric match by varying the current. Red glass, Jena 2,745, or preferably F 4,512, mounted at the ocular furnishes a high quality of monochromatic light. The relation between the current through the lamp and the temperature has the form

$$i = a + bt + ct^2 \tag{54}$$

Three standardization points are necessary to determine the constants $a$, $b$, $c$. The lamps should not be used at temperatures higher than 1,500 deg. cent. (for the highest accuracy 1,300 deg. cent.) on account of deterioration of the filament. By proper care they may be used for hundreds of hours without appreciably altering the calibration. For temperatures higher than 1,500 deg. cent. black absorption glasses (Jena F 3,815) or sector discs are used to cut down the intensity of light from the furnace. The relation between the observed temperature and the true temperature follows from Wien's law:

$$\text{Log}\,(1-A_\lambda) = \frac{c_2 \log e}{\lambda}\left(\frac{1}{T_2}-\frac{1}{T_1}\right) \tag{55}$$

where $A_\lambda$ is the absorption coefficient of the glass or sector, $c_2 = 14{,}500$, $\log e = 0.4343$, $\lambda$ is the mean wave length of the red glass, $T_1$ the absolute temperature observed when sighted through the disc or glass and $T_2$ the absolute temperature of the furnace. All lamps should be aged before using by heating at 1,800 deg. cent. for a period of 20 hr.

**373. Emissivity corrections for optical pyrometers.** Optical pyrometers will indicate true temperatures when sighted upon a black body. Black-body conditions are approximated in practice by a peep-hole in the side of a furnace or kiln, or a closed porcelain tube thrust into molten metals or salts. When sighting upon objects in the open, certain corrections must be applied. The relation between the emissivity (monochromatic light)

Digitized by Google

of a substance and its observed and true temperature follows from Wien's law:

$$\left(\frac{1}{T}-\frac{1}{S_\lambda}\right)=\frac{\lambda}{c_2 \log e}\log A_\lambda \qquad (56)$$

where $T$ is the true absolute temperature of the substance, $S_\lambda$ the apparent absolute temperature as measured by an optical pyrometer using light of wave length $\lambda$ measured in microns, and $A_\lambda$ is the absorption or emissivity at the wave length $\lambda$ and temperature $T$. The following table (Par. **374**) presents the emissivities of various substances determined for red light ($\lambda = 0.65\mu$).

**374. Table of Emissivities For Red Light** ($\lambda = 0.65\mu$)

| Substance | | A | Substance | | A |
|---|---|---|---|---|---|
| (*a*) Silver | | 0.07 | Cuprous oxide | | 0.70 |
| (*b*) Gold | solid | 0.13 | Iron oxide | | 0.85 |
| | liquid | 0.22 | Porcelain | | 0.25 to 0.50 |
| Platinum | | 0.33 | Lime | | 0.10 to 0.40 |
| Palladium | | 0.33 | (*c*) Molybdenum | 1,000° | 0.44 |
| (*a*) Copper | solid | 0.11 | | 2,400° | 0.37 |

Authority (*a*) Stubbs; (*b*) Stubbs and Prideaux; (*c*) Mendenhall and Forsythe; (*d*) Bidwell; (*e*) Burgess and Foote; (*f*) Burgess and Waltenberg.

**375. Curve of emissivity corrections.** Fig. 132 shows the corrections to apply to the pyrometer readings for a number of values of $A$, using $s$ deg. cent. as abscissas and $(t-s)$ deg. cent. as ordinates. To obtain the true temperature corresponding to an observed temperature $s$ deg. cent., add to $s$ the value of the ordinate at the particular emissivity $A$ and abscissa $s$. As an example, let $A = 0.30$, $s = 2{,}000$ deg. cent.; true temperature $= 2{,}000 + 320 = 2{,}320$ deg. cent.

**376. Recording pyrometry.** Among the different methods for the measurement of high temperatures, several may be made continuously re-

Digitized by Google

cording. Forms of temperature recording apparatus suitable for laboratory investigation have been in existence for years. Of late a number of manufacturers have produced recorders which serve most satisfactorily in the technical industries.

**377. Applicability of recording pyrometers.** The following pyrometers have been made recording: (*a*) constant-volume gas thermometer; (*b*) thermoelectric pyrometer; (*c*) electrical resistance thermometer; (*d*) total radiation pyrometer; (*e*) transpiration pyrometer. The optical pyrometer of the Morse type could be made semi-recording, but the other optical and discontinuous types of pyrometers could be made recording only with very great difficulty.

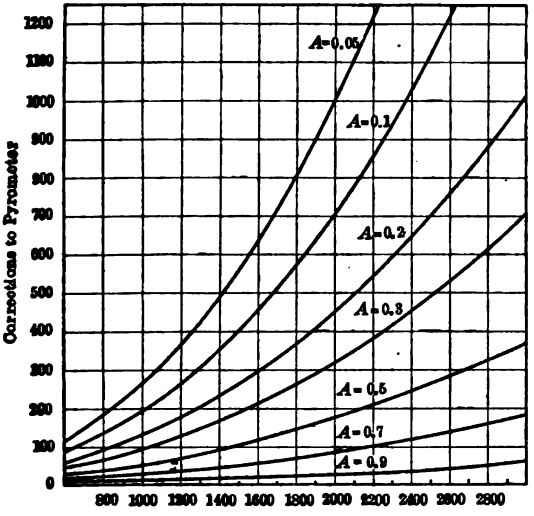

FIG. 132.—Correction curves for optical pyrometers.

**378. Types of curves of recording pyrometers.** The simplest and most universal application of recorders is to obtain the time-temperature curve ($t$ vs. $\theta$) where time and temperature, or some quantities proportional to them, appear as the coordinates. This type of curve is especially valuable as a continuous record of the temperatures of a furnace or kiln during a prolonged run. Sometimes it is also used to detect recalescence points in steel, which appear as flexures or indentations on the plot, when the furnace containing the sample is uniformly heated or cooled. Occasionally the temperature-rate curve ($\theta$ vs. $d\theta/dt$) is employed for this purpose, and very commonly in metallography the inverse rate curve ($\theta$ vs. $dt/d\theta$) is used. The inverse-rate curve is obtained by noting the time intervals necessary to cool (or heat) the specimen by equal decrements of temperature. In these methods accidental variation in the temperature of the furnace is recorded. This is desirable in case the changes in the temperature of the furnace or contents are desired, but when the transformations which are taking place within the sample itself are being investigated, such fluctuations

Digitized by Google

should be eliminated. This may be done by taking the differential temperature curve ($\theta$ vs. $\theta - \theta'$), or recording the temperature of the sample in terms of the successive differences in temperature between the sample and another body called the neutral, possessing no transformation points, and placed within the furnace close to the sample. The relations involved in the differential-temperature curve are usually better interpreted by means of the derived-differential curve, or the temperature difference between the sample and the neutral for equal temperature decrements vs. $\theta$. The form of curve thus obtained is similar to the inverse rate curve.

**379. Standard temperatures.** From a consideration of determinations made since 1900, and selecting only temperatures in the location of which two or more independent observers have participated, and which are suitable for use as check points in physical and chemical operations, the following table is presented (Par. **380**). Temperatures above 1,550 deg. cent. are based on $c_2 = 14{,}500$. Boiling-points are given for a pressure of 760 mm. Hg.

**380. Table of Standard Temperatures; Thermodynamic Scale (deg. cent)**

| Substance | Phenomenon | Temperature | Uncertainty | Reproducibility |
|---|---|---|---|---|
| Hydrogen | Boiling | −252.7 | 0.2 | 0.05 |
| Oxygen | Boiling | −182.9 | 0.1 | 0.03 |
| Carbon dioxide | Sublimation in inert liquid. | −78.34 | 0.1 | 0.03 |
| Mercury | Freezing | −37.7 | 0.1 | 0.05 |
| Water | Freezing | 0 | 0 | 0.001 |
| $Na_2SO_4 + 10H_2O$ | Transformation to anhyd. salt. | 32.383 | 0.002 | 0.001 |
| Water | Boiling | 100 | 0 | 0.001 |
| Naphthalene | Boiling | 217.96 | 0.02 | 0.01 |
| Tin | Freezing | 231.85 | 0.1 | 0.05 |
| Benzophenone | Boiling | 305.90 | 0.05 | 0.02 |
| Cadmium | Freezing | 320.92 | 0.1 | 0.03 |
| Lead | Freezing | 327.4 | 0.1 | 0.05 |
| Zinc | Freezing | 419.4 | 0.1 | 0.15 |
| Sulphur | Boiling | 444.6 | 0.1 | 0.03 |
| Antimony | Freezing | 630.0 | 0.5 | 0.3 |
| Ag.Cu | Eutectic freeze | 779 | 1 | 1 |
| NaCl | Freezing | 800 | 2 | 1 |
| Silver | Freezing | 960.5 | 1.0 | 0.5 |
| Gold | Freezing | 1063 | 2 | 1 |
| Copper | Freezing | 1083 | 2 | 1 |
| Palladium | Freezing | 1549 | 10 | 3 |
| Platinum | Melting | 1755 | 15 | 5 |
| Alumina | Melting | 2050 | 30 | 20 |
| Tungsten | Melting | 3000 | 100 | 25 |
| Carbon arc | Pos. crater | 3600 | 150 | 50 |
| Sun | Surface | 6000 | 500 | 100 |

| | |
|---|---|
| Oxygen boiling-point* | $t = -182.9 + 0.013\,(p-760)$ |
| Carbon dioxide, sublimation point. | $t = -78.34 + 0.017\,(p-760)$ |
| Water, boiling-point | $t = 100 + 0.037\,(p-760)$ |
| Naphthalene, boiling-point. | $t = 217.96 + 0.058\,(p-760)$ |
| Benzophenone, boiling-point. | $t = 305.90 + 0.063\,(p-760)$ |
| Sulphur, boiling-point | $t = 444.6 + 0.0912(p-760) - 0.000042\,(p-760)^2$ |

Of the boiling substances, benzophenone and oxygen are the only ones to the purity of which special attention need be given, but the metals used for freezing- or melting-points must be of the *highest* purity.

* $p$ denotes pressure in mm. of Hg.

## HEAT CONDUCTIVITY

**381. Heat Conductivity.** Three processes exist by means of which heat may be transferred from one body to another, by radiation, by convection and by conduction. All of these factors enter into the computation of the heat losses from a furnace, but frequently the loss by convection and radiation may be made small or negligible in comparison with the loss by conduction. The quantity of heat which flows through a plate of area A and thickness $e$ in a time $t$ is expressed,

$$Q = k(\theta_1 - \theta_2).A\ t/e \qquad (57)$$

where $\theta_1$ and $\theta_2$ are the temperatures upon each side of the plate (a plate theoretically infinite in extent) and $k$ is known as the **thermal conductivity.** $k$ is defined by the quantity of heat which flows per unit time through unit area of a plate of unit thickness, having unit difference of temperature between its faces. Numerically $k$ is usually expressed as the quantity of heat in small calories which is transmitted per second through a plate 1 cm. thick, per square centimeter of its surface, when the difference in temperature between the two faces is 1 deg. cent. $Q$ then refers to g-cal., $\theta$ to deg. centigrade, $A$ to square centimeters and $t$ to seconds. $k$ is found to vary with the temperature of the plate and is expressed approximately by the equation

$$k_t = k_o(1 + \alpha t) \qquad (58)$$

where $t$ is the temperature centigrade and $\alpha$ a constant. As an example be it required to find the quantity of heat lost per hour by conduction through a section 100 cm. by 100 cm. of a fire-brick furnace wall 20 cm. thick, the conductivity being 0.00028 cal./(cm.-sec.-degree) and constant with temperature, the inside temperature of the furnace being 1,500 deg. cent. and the outside 300 deg. cent.

$$Q = 0.00028\ \frac{1,500-300}{20}\ 100 \times 100 \times 3,600 = 605,000 \text{ g.-cal.}$$

# FUEL AND GAS ANALYSIS

### BY F. MALCOLM FARMER, M.E.

**383. The purpose of this section** is to indicate very briefly the more important features in connection with fuel and gas analysis. For further information, the reader is referred to the numerous publications on fuel and gas analysis. See Par. 398.

**384. Coal for steaming or producer purposes is usually subjected only to a proximate or engineering analysis,** which includes the determination of the heating value and the percentages by weight of moisture, fixed carbon, volatile matter, sulphur and ash. When a complete or ultimate analysis is made, the components of the volatile matter are also determined.

**385. The details of manipulation in coal analyses** have a marked effect on the result and since many of the determinations are made in a manner more or less arbitrary, care should be taken to conform to standard practice. The American Chemical Society and the American Society for Testing Materials are jointly preparing standard specifications, and until they are completed their interim reports are the basis of the most generally accepted practice in this country.*

* The latest report is given in *The Journal of Industrial and Engineering Chemistry*, June, 1913, p. 517. The proposed specifications are given in complete detail.

Digitized by Google

**386. The sampling of coal** is of the utmost importance. **The greatest** care is necessary in order to obtain a sample which is truly **representative** of all of the coal in the lot which the sample is to represent. **In general, a** largo sample of 100 to 200 lb. should be made up of small **quantities taken** from various parts of the entire lot. This is gradually reduced **to a 2-lb.** sample about pea size, by crushing, mixing and quartering.*

**387. Heating values of fuels** are determined with **calorimeters**, or instruments in which the heat evolved by the combustion of a **sample of the** fuel is absorbed by water, the weight and rise in temperature of **which are** observed. There are two general classes, the non-continuous **class** in which only a small quantity of the fuel (solid or liquid) is burned **at one time**, and the continuous class where the fuel (liquid or gaseous) **flows continuously** through the calorimeter.

**388. The Berthelot or bomb type calorimeter** of the **non-continuous class** is most generally used for high-grade commercial work. **Fig. 133** shows the arrangement of parts in an **Atwater-Mahler calorimeter**, **which** is similar to the Mahler, Emerson, Hempel and other well-known **bomb calorimeters.** The "bomb" is the strong steel vessel, *B*, with **closely** fitting screw-top and lined with platinum, gold, nickel, enamel or other non-corrosive material. A valve is provided at the top for supplying oxygen. The sample is placed in the crucible, *C*, and ignited by the very fine iron wire, *I*, which is heated to incandescence by an electric current through *W* and *W'*. The bomb is placed in the calorimeter vessel proper, *Q*, which is filled with water. Heat insulation is provided by placing the calorimeter in two other vessels, *T* and *V*, separated by air spaces. The water is agitated by the stirrer, *S*, and its temperature measured with a thermometer, *t*.

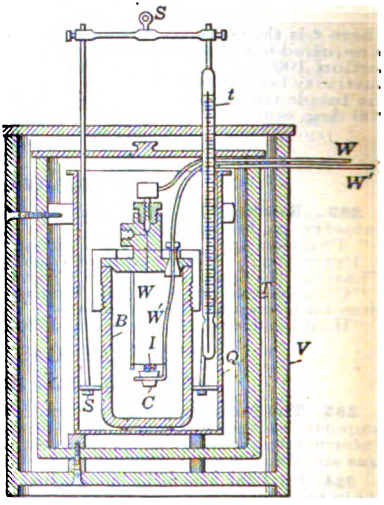

FIG. 133.—Atwater-Mahler fuel calorimeter.

**The procedure in operation** is briefly as follows: About 1 g. of coal is carefully weighed in the crucible, which is placed in the bomb with the fine iron wire carefully arranged in contact with the coal. After the top is screwed on the bomb is filled with oxygen at a pressure of 300 lb. to 450 lb. per sq. in., and placed in the calorimeter tank, which contains a known weight of water. After the initial "radiation" rate is obtained, the specimen is ignited and the rise in temperature of the water observed. When the rate of change of temperature becomes constant, the final "radiation" rate is obtained. The heating value per pound is calculated from the weight of the specimen, the weight of the water and the rise in temperature. Correction is made for the heat capacity of the calorimeter ("water equivalent"), the "radiation" during the combustion interval, the heat from the electric energy used in heating the wire and the heat of combustion of the latter. The temperature range is only a few degrees centigrade and is usually

* Excellent detailed instructions are given in Bulletin No. 339, U. S. Geological Survey, and in later bulletins of the Bureau of Mines on coal sampling. Also see books and technical articles on coal specifications.

Digitized by Google

measured with differential mercury thermometers, read to 0.001 deg. with the aid of a microscope.

**389. The essential details of procedure for a proximate analysis** are as follows: (1) The whole sample is placed in a shallow pan and air-dried in a special oven at 10 deg. or 15 deg. cent. above room temperature until the weight is practically constant (from 2 to 4 hr.) The loss in weight is the **surface moisture** or **"air-dry" loss.** The sample is then ground in a coffee mill until it will pass through a 20-mesh sieve;* it is next quartered and then about 100 g. are ground in a mortar or ball mill to 80 or 100 mesh.

(2) **Total moisture** is obtained by heating 1 g. of the final sample in an open porcelain or platinum crucible in an oven at 104 to 107 deg. cent., and noting the loss in weight.

(3) **Volatile matter** is obtained by heating 1 g. in a special, covered platinum crucible at a bright red heat in a Bunsen flame for 7 min. The total loss in weight is equal to the volatile matter plus the moisture.

(4) **Ash** is determined by burning 1 g. of the sample in an open crucible until the weight is constant (1 to 2 hr.). The highest temperature of the Bunsen flame is utilized. Sometimes a small stream of oxygen at low pressure is injected into the crucible to hasten combustion.

(5) **Fixed carbon** is determined by calculation, that is, fixed carbon = 100 − (moisture + volatile matter + ash), all expressed in per cent.

(6) **Sulphur** is determined as follows: 1 g. of the coal is mixed with suitable chemicals (such as magnesium oxide and sodium carbonate) and burned. The residue is extracted with water, filtered, and the sulphur precipitated from the solution with barium chloride, coming down as barium sulphate. From the weight of this precipitate, the percentage of sulphur in the original sample is calculated.

**390. The Junker calorimeter** is the best known example of the **continuous class.** It is used extensively for gas fuels and can also be used for liquid fuels. Fig. 134 shows the calorimeter set up for gas testing. The

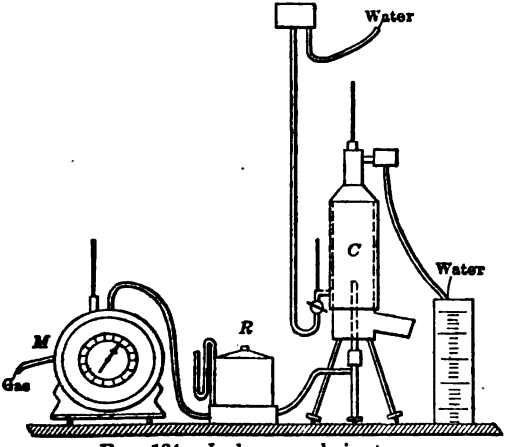

FIG. 134.—Junker gas calorimeter.

gas flows through the meter *M* and a pressure regulator *R* to a special Bunsen burner inside of the calorimeter *C*. The combustion chamber is surrounded by a chamber through which water flows at a constant rate. The heating value in B.t.u. per cubic foot of gas is calculated from the rate of gas consumption, rate of flow of the water and the difference between the average

* 20 clear spaces per linear inch.

Digitized by Google

inlet and average outlet water temperatures. For liquid fuels, a weighing device and a special burner are provided.

**391. Other types of calorimeters** of the **discontinuous class** differ essentially from the Berthelot only in the method of supplying the **oxygen**. In calorimeters of the Carpenter and the Favre and Silberman type, **oxygen** gas is supplied at atmospheric pressure. In instruments of the Parr class, the oxygen is supplied by chemicals with which the sample is mixed.

**392. Fuel oils** are, in addition to the foregoing, Par. **390**, frequently tested for **flash-point**, or temperature where the vapor given off will ignite but will not continue to burn; **fire-point**, or temperature where combustion will continue if the vapors are ignited; **viscosity**; **chill-point**, or congealing temperature; per cent. of asphaltum.

**393. Reports of proximate analyses** and heating value (in B.t.u. per pound) usually give the results calculated on at least two bases, "**as received**" and "**dry**." The former are of most interest to the users of the fuel, but the results must be reduced to the latter basis when comparisons are to be made.

**394. Fuel or illuminating gases are analyzed** for the following **components in per cent. by volume**; **carbon dioxide** ($CO_2$), **carbon monoxide** (CO), **oxygen** ($O_2$), **methane** ($CH_4$), **ethylene** ($C_2H_4$), **hydrogen** ($H_2$) and **nitrogen** (N). CO, $CO_2$, $O_2$ and $C_2H_4$ are usually determined by passing a known volume of the gas through a series of reagents, one at a time, each of which will absorb one, and only one, of the components. The diminution of the volume is noted after each absorption. $H_2$ and $CH_4$ are obtained by combustion in a glass tube with a known volume of air, the products of combustion being measured by absorption as in the case of the other constituents, and the original volume calculated. N is obtained by difference.

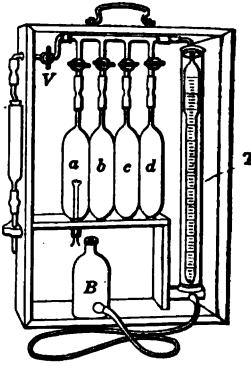

FIG. 135.—Orsat apparatus.

**395. Orsat apparatus.** The various forms of apparatus which employ the **absorption method** are based on the principle of the Orsat apparatus shown in Fig. 135. A given quantity of gas, usually 100 c.c., is drawn into the measuring tube, *T*, by means of the water bottle, *B*, and carefully measured. The gas is then forced into the $CO_2$ reagent bottle, *d*, drawn back into *T* and the decrease in volume noted. The process is repeated with each of the tubes, *c*, *b* and *a*, giving the percentages of $O_2$, CO, and $H_2$ respectively. The usual **reagents** are caustic potash solution for $CO_2$, ammoniacal cuprous chloride solution for CO and alkaline pyrogallic acid solution for $O_2$, $H_2$ being obtained by combustion.

**396. Flue gases** are analyzed for **carbon dioxide** ($CO_2$), **carbon monoxide** (CO), **oxygen** ($O_2$), **hydrogen** ($H_2$) and **nitrogen** (N), in the manner indicated for fuel or illuminating gas.

**397. $CO_2$ recorders** are instruments which automatically and continuously remove samples of flue gas and indicate with a pointer or record on a clock-driven chart the percentage of $CO_2$ in each sample. Various principles are employed, among which are the variation in the refraction index with the percentage of $CO_2$, the variation in density compared with air as a standard, and the variation in the position of a float with the volume remaining after the $CO_2$ has been removed with caustic potash, the usual reagent.

## WATER, GAS, AIR AND STEAM METERS

BY REGINALD J. S. PIGOTT

### WATER METERS

**399. Classification.** Water meters are of three classes: weighing, volumetric and velocity.

**400. Water weighers** are not affected by variations in temperature and allow, approximately, 2 per cent. error. All weighers must be fed with a gravity flow. The various methods employed by concerns manufacturing water weighers are described in Par. **401** to **404.**

**401. Worthington weigher.** In this device two counterweights are mounted on trunnions, water flowing into one tank while the other empties. As the water rises the centre of gravity of the tank and water is shifted, finally

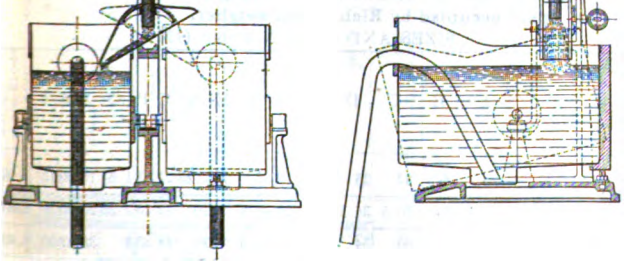

FIG. 136.—Worthington recording liquid weigher.

reaching a point where the tank upsets and empties. This movement automatically throws the water deflector over to fill the other tank. See Fig. 136. This device will, of course, weigh only in units corresponding to the weight contained in one tankful; the number of trips of the tanks being auto-

Digitized by Google

matically taken by a counter and multiplied by the tank unit weight. The accuracy approximates 2 per cent. See Par. **400.**

**402. The Richardson weigher,** Fig. 137, uses a single weighing tank mounted on knife-edged scale beams directly counterbalanced. The overbalancing of the weighing tank trips the feed valve from the upper reservoir and opens the discharge. By a system utilising two toggles and dead-centres, the upper valve does not open till the outlet valve is again entirely closed. See Par. **400.**

**403. The Wilcox weigher** operates as a single tank with a syphon outlet. The bell float and standpipe (which is open top and bottom), are down normally, so that the standpipe seals the opening in the diaphragm between upper and lower tanks. Water accumulates in the upper section until it overflows the top of the standpipe and runs down into the lower compartment, trapping air in the bell and inner legs of the two siphons, and raising the bell. As the water rises, the trapped air is compressed until finally it breaks through the trip seal and starts the main siphon. The release of air pressure allows the bell and standpipe to drop, and the cycle begins again. See Par. **400.**

**404. Volumetric meters** include measuring-tank meters (other than weighers), piston meters and disc meters. Variations in temperature affect all these types, so that they must be calibrated for the average temperature on which they are to be used. Accuracy of piston and disc meters should be marred by only 1.0 to 1.5 per cent. average error, provided they are properly used and not worn. Wear of piston meters or disc meters, causing leakage, may increase the percentage of average error to 5 or 10 per cent. The various types of volumetric meters are described in Par. **406** to **408.**

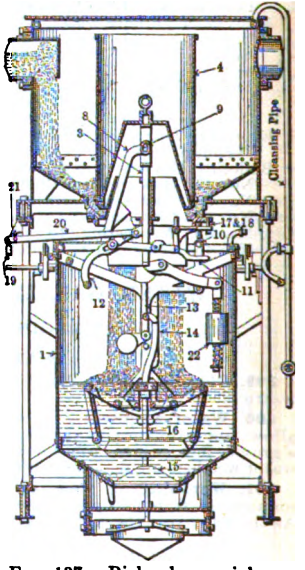

FIG. 137.—Richardson weigher.

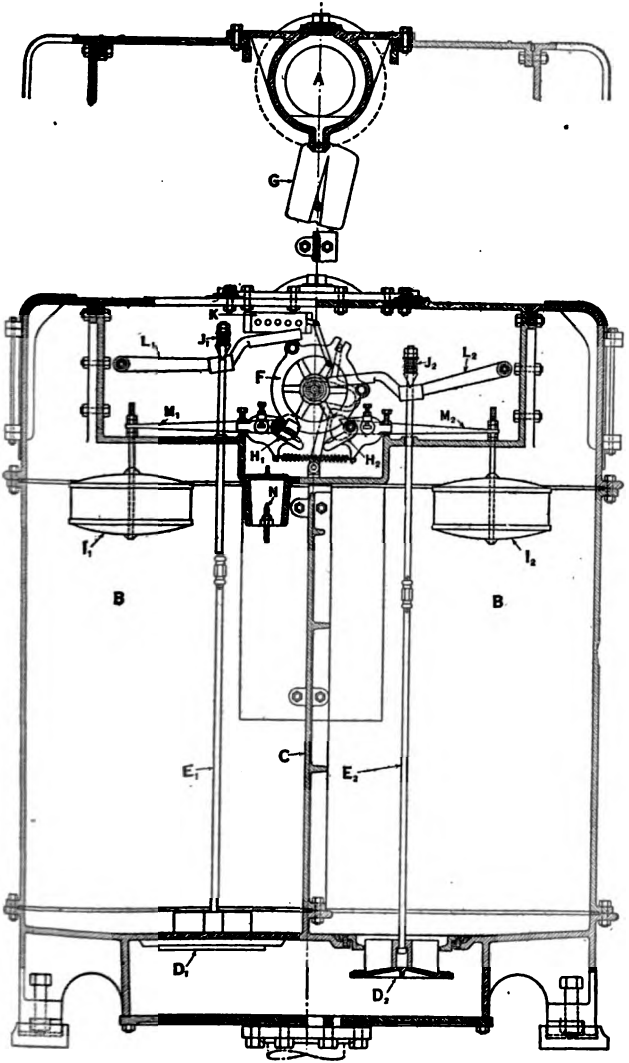

FIG. 138.—Hammond water meter.

Digitized by Google

**406. The Hammond measuring-tank meter,** Fig. 138, consists of two tanks, $B_1$ and $B_2$, into one of which the inflowing water is directed by the baffle $G$, while the other is emptying through the valve $D_2$. When the water level in $B_1$ rises high enough to lift float $I_1$, latch $H_1$ releases, the weight of water on valve $D_1$ throws the wrist plate over, opening $D_1$ and closing $D_2$, and changing the deflector $G$ to fill $B_2$. The action is very rapid at the release period, preventing loss of water during the change period. A gage, $N$, is included for accurately setting the meter. This device, as with all the volumetric meters, is affected by change of temperature. For variations of approximately 50 deg. fahr. (28 deg. cent.) the error is not great, the average being 2 per cent. to 3 per cent. It is operated on gravity flow.

**407. Disc meters** of the general type in Fig. 139, operate by the gyration of a disc in a spherical chamber. The stem attached to the disc describes a circular path and operates the counter. These meters are used on closed lines under pressure.

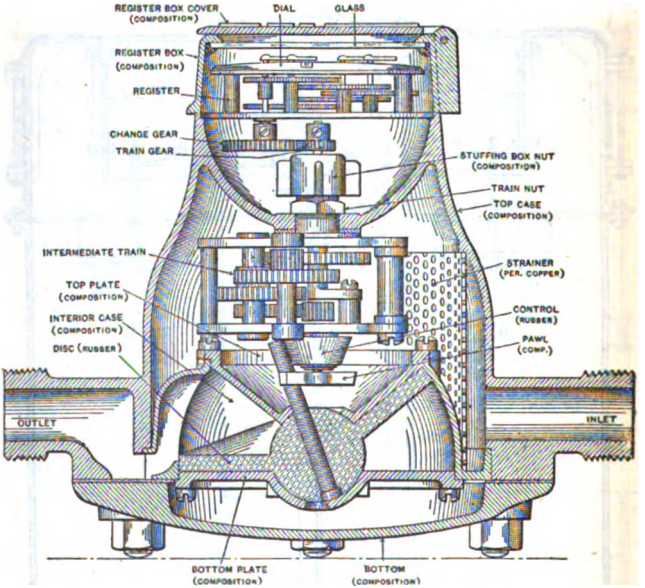

FIG. 139.—Worthington disc meter.

**Disc meters vs. piston meters.** Disc meters are used chiefly for small lines, up to about 3 in. diameter. Piston meters for sizes from 2 in. to 8 in. For larger flows, tank, Venturi or turbine meters are generally employed.

**408. Piston meters** of the general type shown in Fig. 140, operate like a duplex steam pump, the movement of the pistons measuring off definite volumes of water per stroke. The strokes are recorded by the counters usually in units of cubic feet. These meters are used on closed lines under pressure, and necessitate, for their operation, a pressure drop of from 2 to 6 lb. per sq. in., depending on the flow.

**409. The Venturi meter** is widely used, both for large and small flow, on pumping service and boiler feed. It occupies practically no space outside of

Digitized by Google

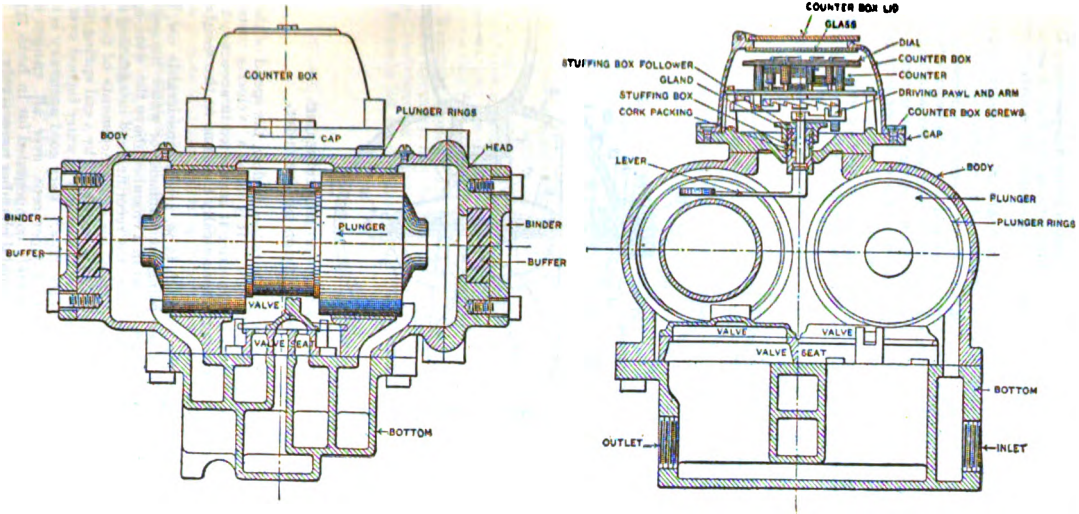

FIG. 140.—Duplex piston meter.

Digitized by Google

the pipe line; has no moving parts in the meter proper, and operates o closed pressure lines. The accuracy is from 1.0 to 1.5 per cent. if used o reasonably steady flow. If used on rapidly fluctuating flow it becomes ver inaccurate. If kept clean, the accuracy is substantially constant during th life of the meter.

A slight pressure drop, 0.25 to 3 lb., occurs through the meter, depending i size on the flow. For theory of the Venturi tube, see Sec. 10.

**410. The Pitot meter** is not satisfactory for general service, as the hea differences are much less than those developed in the Venturi, consequentl the registering apparatus is much more delicate and sensitive to leakage in th pressure lines leading from the main to the recording instrument. It is als very sensitive to eddies in the pipe lines in which the Pitot tube is insertec For the theory of the Pitot tube, see Sec. 10.

**411. The turbine meter**, Fig. 141, is used to some extent for large-siz lines and large flow. It operates like a hydraulic turbine, and as the mete

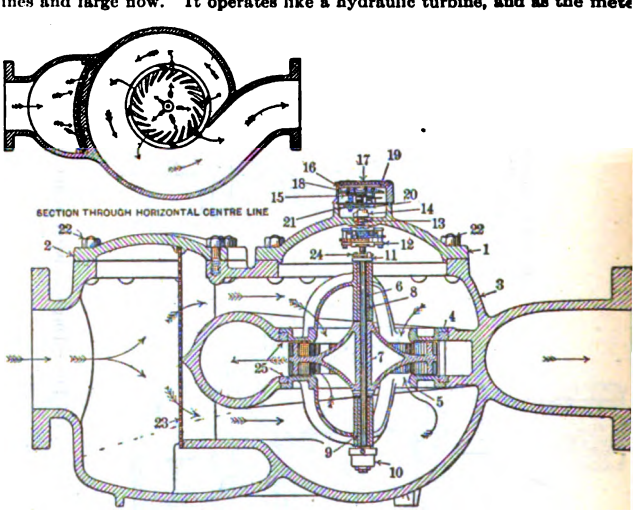

FIG. 141.—Worthington turbine meter.

opposes practically no friction or pressure loss to flow, the speed of the mete is substantially proportional to the flow. It is called a "velocity meter," bu strictly speaking, this meter is volumetric; it is affected in accuracy by ten perature changes. The accuracy is practically the same as the weighers ar tank meters (Par. 400).

**412. Weirs**, usually of the V-notch type, are in considerable use, in co nection with indicating and recording mechanisms for water measuremen (See Sec. 10.) In the **Lea type**, a float in a chamber above the weir, operat a grooved drum in such a fashion that the recording and integrating appar tus move over equal increments of space for equal increments of flow.

In the **Hoppes type**, a conoidal float is suspended by a coil spring, and is shaped that the descent of the float by the weight of water forced over by th rise of the weir, is proportioned to the flow. Very good accuracy is claime for these weir meters, from 0.5 to 1.3 per cent. over all ranges of flo Temperature changes are approximately compensated for in both types, b the behavior of the float and the conoidal chamber respectively.

## GAS METERS AND AIR METERS

**413. The meters available for gas and air measurement are:** (a) bellows-type, for low pressure chiefly; (b), Thomas electric, for high or low pressure; (c) Venturi-tube and Pitot tube and types for high or low pressures; (d) wet types for low pressure; (e) rotaries.

**414. The bellows type "dry" meter** has usually a pair of leather bellows operating two diaphragms, after the manner of a piston in a reciprocating engine. The valve operation is exactly like that of a two-cylinder double acting engine with quartering cranks. The movement of the diaphragms measures off volumes of gas. The pressure and the temperature must be kept reasonably constant, as the accuracy of the meter is affected by both. The error may range from 3 per cent. "slow" to 2 per cent. "fast."

**415. The wet meter** is now used chiefly for large gas-works service, and its operation is somewhat like that of a rotary engine. The average error is usually from 3 per cent. slow to 2 per cent. fast. The obtainable accuracy with large wet meters is within 0.1 per cent.

**416. The Thomas electric gas meter** consists of an electric resistance heater coil in the gas main, a wattmeter and two screen-resistance thermometers. An amount of current is passed through the heater such that the difference of temperature of the gas before and after passing the heater is a definite amount as measured by the screen thermometers, which automatically average the temperature.

The relation between the temperature, watts input and flow is then

$$W = \frac{0.05686\,E}{ts} \qquad \text{(lb. gas per min.)} \qquad (59)$$

where $t$ = temperature difference, inlet and outlet, deg. fahr.; $s$ = specific heat at constant pressure of air or gas measured; $E$ = watts input. The Thomas meter is used as a substitute for the huge wet meters formerly employed at gas houses for the main-flow measurement. Its accuracy is higher than that of any other device now in use for air or gas flow, the error being from $\pm 0.05$ to $\pm 0.2$ per cent. In small sizes it is too expensive to compete with other types of meter, but in large sizes it is much less expensive in proportion, and has the additional advantages of indicating and recording as well as integrating. In commercial service it is generally equipped with an automatic regulator arranged to keep a constant temperature difference between inlet and outlet; the electric instruments can then be graduated directly in pounds or cubic feet, as the flow is directly proportional to the watts input.

**417. Venturi meters** are in some use for large gas-flow measurements: the device is accurate, but the formula for its use is complicated and no satisfactory direct-reading indicating or recording device has yet been introduced.

The formula for air and gas service is

$$W = CA_2 \left(\frac{P_2}{P_1}\right)^{\frac{1}{\gamma}} \sqrt{2g\frac{\gamma}{\gamma-1}\,P_1\delta_1 \left[\frac{1-\left(\frac{P_2}{P_1}\right)^{\frac{\gamma-1}{\gamma}}}{1-\left(\frac{A_2}{A_1}\right)^2\left(\frac{P_2}{P_1}\right)^{\frac{2}{\gamma}}}\right]}$$

(lb. gas or air per sec.) (60)

Where $A$ = upstream area, sq. ft.; $A_2$ = throat area, sq. ft.; $P$ = upstream pressure, lb. per sq. ft.; $P_2$ = throat pressure, lb. per sq. ft.; $\gamma$ = ratio sp. heat at constant pressure to sp. heat at constant volume; = 1.408 for air, = 1.266 for natural gas; $\delta_1$ = density, lb. per cu. ft. at upstream section; $C$ = 0.98, coefficient of flow; $g$ = gravitation constant, 32.2.

For differences of pressure less than 20 in. of water, the hydraulic formula may be employed without error in excess of 1 per cent.

$$Q = 18.3\,\frac{A_2}{\sqrt{1-\left(\frac{A_2}{A_1}\right)}}\left(\frac{h\left(\frac{P_2}{P_1}\right)^{\frac{1}{\gamma}}}{\delta_1}\right)^{1/2} \qquad \text{(cu. ft. per sec.)} \qquad (61)$$

Digitized by Google

where $Q$ = cu. ft. per sec. ($= W/\delta_1$); $h$ = difference of pressure, upstream and throat in in. of water [$= (P_1 - P_2)(12/62.35)$].

**418. The Pitot-tube formula for gas and air**

$$Q = 218.44 E d^2 \frac{T_s}{P_s} \sqrt{\frac{hP}{TG}} \text{ (cu. ft. gas or air per hr.)} \quad (62)$$

where $E$ = flow factor of the tube expressed as a decimal; $d$ = internal diam. of tube (in.); $T_s$ = absolute fahr. temperature of measurement base; $P$ = absolute pressure of measurement base, lb. per sq. in.; $G$ = sp. grav. of gas referred to air; if air is measured, $G = 1$; $P$ = absolute static pressure of flowing gas in meter, lb. per sq. in.; $T$ = absolute temperature fahr. of flowing gas; $h$ = velocity head of flowing gas (in. of water); $Q$ = cu. ft. of gas per hr. at $T$ and $P$.

The value of $E$ is 0.8530 for smooth tubes, 2-in. to 5-in. diameter, with the Pitot tube placed exactly in the centre of the pipe. The velocity is a maximum at the centre of a pipe, decreasing to a minimum at the pipe surface. This accounts for the fact that $E$ is less than unity when the Pitot tube is at the centre of the pipe. The coefficient of flow for the Venturi meter approximates from 0.97 to 0.98 for properly designed meters.

**419. Rotary meters** of several makes are on the market; one type is shown in Fig. 142, intended for compressed-air service. Air enters the chamber at $C$ and impels the flap pistons $D$ and $E$ toward the outlet side. As the pistons $J$, $K$, and $L$, are closed on the return side, the pressure area is greatest on the under side, causing the meter to turn.

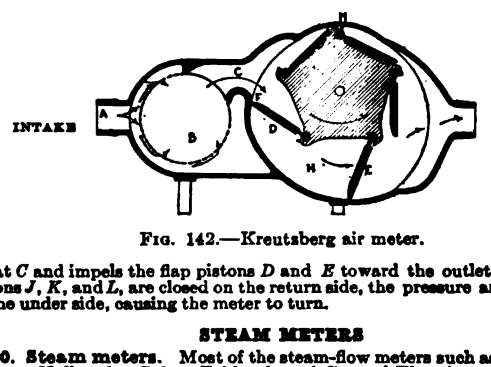

FIG. 142.—Kreutzberg air meter.

## STEAM METERS

**420. Steam meters.** Most of the steam-flow meters such as the St. John Sargent, Hallwachs, Gehre, Eckhardt and General Electric, can be used on compressed-air service if desired. See Par. 419. Steam meters are divided into area meters (Par. 421 and 422) and velocity meters (Par. 423 and 424). Pressure and quality variation affect the accuracy of all area and velocity meters, so that the meters are only correct for the calibration conditions of pressure and quality, unless fitted with compensating devices.

**421. "Area" steam meters.** In this class are those in which a disc or cup partially closes an opening through which steam is passing. The shape of the passage or of the cup is so arranged that as it rises from zero position, the free area for passage of steam is increased. As demand for steam is increased, the increase of pressure drop past the disc or cup, causes it to move further up the passage, enlarging the area till the pressure drop is reduced and the disc again in equilibrium. The movement of the disc is communicated to an indicator and chart graduated in lb. per hr. flow. The passage is so designed that the movement of the disc or cup is directly proportional to the flow, giving an equal increment reading.

**422. The Sargent meter** is an example of the area type. It has a conical cup seating over a conical seat. As the stream flow is increased, the cup rises, exposing more area for flow between cup and seat. As the weight of the cup and stem is the only load, the pressure difference is constant. A pressure compensator in the form of a Bourdon tube carrying the indicating needle, is

Digitized by Google

attached to the bottom of the stem, and the combined rise and translation of the needle, due to the Bourdon tube and the cup, is read off on a series of weight-flow curves placed behind the needle. The accuracy will be about 2 per cent. if very well adjusted. The pressure compensation is likely to reduce the total error, which will average between ±2 and ±3 per cent. in ordinary service.

**423. Pressure indicating devices for use with velocity steam meters.** All the velocity meters, Venturi, Pitot and orifice types, require some form of sensitive differential gage which will accurately measure a small difference between two high initial pressures.

The simplest indicating apparatus consists of a glass water—or mercury—U tube. To this class belong the Gebhardt, Gehre and General Electric.

**424. The Gebhardt steam meter,** Fig. 143 is given as an example of the gage-glass type of velocity meter and reads directly by a water column on a chart graduated in lb. per min. or per hr., and for a complete range of pressures. To read the meter correctly, it is necessary to know the pressures and quality. By means of a small condensing chamber this meter is made suitable for use with superheated steam. Accuracy of the Gebhardt meter (also the G. E. type $TS_3$ and Gehre) is ±1 per cent. on careful handling, but more usually ±1.5 to 2 per cent. in ordinary service without constant pressure and quality check.

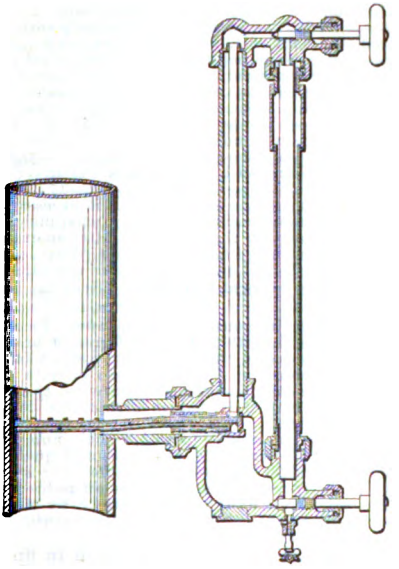

FIG. 143.—Gebhardt steam meter.

**The Thomas electric meter can be used for measuring steam very accurately,** but it cannot be commercially employed as the amount of current required becomes excessive (on account of the high specific heat of steam) and especially for wet steam where moisture must be evaporated.

**425. Steam-meter costs.** At the present time there are available at least two indicating meters, one suitable for general testing, and one for the boiler or engine room as permanent instruments. Of the recording instruments, while one or two are fairly satisfactory in operation, the price of all is much too high for general adoption. There is nothing about these instruments which should prevent their manufacture and sale in the same manner and at about the same price as high-grade recording gages.

## PRECISION OF MEASUREMENTS

### BY WILLIAM J. DRISKO

**426. Classification of measurements.** For convenience of treatment all measurements are classified as either direct or indirect. **A direct measurement** consists in determining the **numeric** which expresses the magnitude of the quantity in terms of some arbitrary unit. Thus lengths determined by means of a graduated scale, time by a clock, volume of a liquid by a graduated flask, etc., are illustrations.

**Measurements are indirect** when the numeric is obtained by some computation making use of some functional relation expressed by a formula,

Digitized by Google

*e.g.*, the density of a sphere expressed by the relation $d = M/(\frac{1}{6}\pi D^3)$, where $M$ is the mass obtained by means of an equal-arm balance and $D$ the diameter measured by a micrometer caliper; or the horse-power of an engine, h.p. = p.l.a.n./33,000, where $p$ is the mean-effective pressure found by measurement, $l$ the length of stroke, $a$ the area of the piston found by measuring its diameter and $n$ the number of strokes per minute found by counting them. In general these expressions take the form,

$$X = F(a, b, c \ldots \quad A, B, C \ldots)$$

where $a$ $b$, $c$ . . . represent measured quantities, while $A$, $B$, $C$ . . . represent constants (like 33,000 and $\pi$ in the above formulæ) and $F$ represents that there is some functional relation between measurements, constants and the indirectly measured quantity $X$.

**427. Every measurement has a definite precision.** Thus the length of a building might be reliable to the nearest quarter inch, the current in a certain circuit to the nearest tenth of an ampere, or the time of vibration of a pendulum to the nearest hundredth of a second. To determine this reliability it is necessary to make a very careful study of all the instruments used, the care with which they are made, graduated, calibrated, adjusted for change of temperature or of position, etc., etc. It furthermore is necessary to know not only the skill of the observer, but also whether any constant errors may be due to his "personal equation." If for instance one desires to calibrate a voltmeter at 110 volts by means of a standard Weston cell, the following points must be considered: How closely must the electromotive force at standard temperature be determined? How closely must the temperature coefficient be determined? If the temperature of the cell when used is determined by means of a mercury thermometer, how closely must the thermometer be calibrated and read? How closely must the resistance of the voltmeter be known and is it necessary to take any precautions regarding its temperature; and lastly, what must be the precision of the variable resistance used for the balance? After an examination of all these probable sources of error the final question is, What is the most probable value of the combined effect of all these separate deviations or errors? (See Par. 1–6.)

**428. The general problem.** Given the functional relation,

$$X = F(a, b, c \ldots) \tag{63}$$

the problem in general is as follows: First case if $a$, $b$, $c$ . . . can be measured each with a definite degree of precision, what is the best representative value of the resultant precision in $X$? Second case: if it is desired to determine $X$ to a certain definite precision, how precisely must each of the components be measured so that the combined effect of all the deviations may not produce a resultant deviation in $X$ greater than the assigned limit?

Unless it is possible to assign some numerical estimate to the precision attained in determining any measured quantity, $X$, the result is of little practical value. Hours of valuable time are often wasted in determining some unimportant component of an indirect measurement with excessive precision, while at the other extreme we often find final results absolutely worthless as the result of failure to measure some important component with the necessary precision.

**429. Determination of precision in final result with known precision in the measured components.** Referring to Eq. 63, let $\delta_a$, $\delta_b$, $\delta_c$ . . . be the numerical deviations or precision measures of the direct measurements $a$, $b$, $c$ . . . ; $\Delta_a$, $\Delta_b$, $\Delta_c$ be the deviations in $X$ due to the deviations in the separate components, and $\Delta$ the combined effect of the separate effects $\Delta_a$, $\Delta_b$, $\Delta_c$ . . . . Then $\Delta/X$ is the fractional deviation or precision measure of $X$ and $\delta_a/a$, $\delta_b/b$, $\delta_c/c$ . . . are the fractional deviations of the components $a$, $b$, $c$ . . . and 100 times the fractional deviation is the percentage deviation. We first find the separate effect of each of these deviations $\delta_a$, $\delta_b$, $\delta_c$ . . . on $X$ and then find the combined effect of these separate effects. The change in $X$ due to a slight change in $a$ ($b$, $c$ . . . remaining constant) is found by differentiating the function with respect to $a$, *i.e.*,

$$\Delta_a = \frac{\partial X}{\partial a}\,\delta a \tag{64}$$

and a similar slight change in any component $k$ would give

$$\Delta_k = \frac{\partial X}{\partial k}\,\delta k \tag{65}$$

Digitized by Google

It can be shown that the most probable value of the resultant effect, $\Delta$, of the separate effects, $\Delta_a, \Delta_b, \Delta_c$ . . . is

$$\Delta = \sqrt{\Delta_a^2 + \Delta_b^2 + \Delta_c^2 + \ldots} \qquad (66)$$

**Example.** The value of the acceleration due to gravity is to be determined by means of a pendulum whose length and time of vibration are to be measured and used in the formula $g = \pi^2 l/t^2$. Here $X$ is $g$, $a$ is $l$, b is $t$ and $\pi$ is a constant. Measurements gave $l = 101.42$ cm., reliable to 0.05 cm. and $= 1.0094$ sec., reliable to 0.0008 sec. How precise is the value of $g$ when computed from this data? Differentiating with respect to $l$, we have, $\Delta_l = \pi^2\delta_l/t^2 = 9.9/1.0 \times 0.05 = 0.50$ cm. per sec. per sec. Differentiating with respect to $t$ we get, $\Delta_t = -\pi^2 l \times 2 \times \delta_t/t^3 = 9.9 \times 100 \times 2 \times 0.0008/1.0 = 1.6$ cm. per sec. per sec. This means that a deviation of 0.05 cm. in the length of the pendulum affects $g$ by only 0.5 cm. per sec. per sec. while a deviation of 0.0008 sec. in the value of $t$ affects the value of $g$ by 1.6 cm. per sec. per sec. The combined or resultant effect would be $\Delta = \sqrt{\Delta_l^2 + \Delta_t^2} = \sqrt{0.5^2 + 1.6^2} = 1.7$ cm. per sec. per sec. and we might write the final result as $g = 981.5 \pm 1.7$ cm. per sec. per sec. which means that the value of $g$, as determined, is probably reliable to the nearest 1.7 cm. per sec. per sec. It should be noted in the above computation for $\Delta_l$, $\Delta_t$ and $\Delta$ that not more than two figures are used in any of the quantities, *i.e.*, $\pi^2 = 9.9$, $t = 1.0$, $l = 100$, etc., the reason being that deviation measures always represent doubtful places. Hence, since more than two doubtful places would be useless, *there is no need of ever keeping more than two figures in each quantity entering into a computation of a deviation measure.*

**430. Determination of necessary precision in measured components to secure desired precision in final result.** The second or converse problem is as follows: $X$ is to be measured to a certain degree of reliability expressed by $\Delta =$ some definite number. What are the allowable deviations $\delta_a, \delta_b, \delta_c$ . . . in each of the measured components $a, b, c$ . . . such that the combined effect, $\Delta$, of their separate effects, $\Delta_a, \Delta_b, \Delta_c$ . . . shall not exceed the prescribed limit? From the law of errors (Eq. 66) an infinite number of solutions is possible. The *best* solution would be that one which, with the least effort on the part of the investigator, would give the assigned precision. The *easiest* solution and the one that has been found satisfactory, at least as a preliminary adjustment of deviations among the various components, is to assume that each of the components may produce an equal effect on the final result, *i.e.*, to let $\Delta_a = \Delta_b = \Delta_c = \ldots \Delta_n$. From this and Eq. 68 it follows that

$$\Delta_a = \Delta_b = \Delta_c = \ldots \Delta_n = \frac{\Delta}{\sqrt{n}} \qquad (67)$$

where $n$ represents the number of measured components. The allowable deviation in any component can then be determined from Eq. 65 and Eq. 67.

**Example.** It is desired to find the heat developed by an electric heater, within three parts in a thousand (0.3 per cent.), by measuring the current used, the voltage at the terminals and the time that the current is flowing. If the pressure is about 110 volts, the current about 0.8 amp. and the time 10 min., how precisely must each component be measured? The formula is $H = I.E.t$, where $H$ is in joules, or $H = 0.8 \times 110 \times 600$ joules $= 52{,}800$ joules. If $H$ is to be reliable to three parts per thousand, it must then be determined to the nearest 158.4 joules, or keeping two figures only, to the nearest 160 joules. Since there are three components, $n = 3$ and we have

$$\Delta_I = \Delta_E = \Delta_t = \frac{\Delta}{\sqrt{n}} = \frac{160}{\sqrt{3}} = 94 \text{ joules.} \quad \text{Differentiating, we get,}$$

$$\Delta_I = 94 = E\delta_I I \quad \therefore \quad \delta_I = \frac{94}{110 \times 600} = 0.0014 \text{ amp.}$$

$$\Delta_E = 94 = I\delta_E E \quad \therefore \quad \delta_E = \frac{94}{0.8 \times 600} = 0.19 \text{ volts}$$

$$\Delta_t = 94 = IE\delta_t \quad \therefore \quad \delta_t = \frac{94}{0.8 \times 110} = 1.1 \text{ sec.}$$

This means that if we assume equal effects and wish to know the heat to the nearest 160 joules, the current must be measured to the nearest 0.0014 amp., the voltage to the nearest 0.19 volts and the time to the nearest 1.1 sec. It

Digitized by Google

would be very easy to reach this precision in the time measurement if a good stop watch were used; in fact this interval could be determined to within 0.2 sec. and therefore the time might be treated as a constant, in which case $n$ would be two instead of three and therefore it would not be necessary to measure $I$ and $E$ quite so accurately as indicated above.

**431. Two classes of formulæ in indirect measurements.** The two methods shown above for the direct (Par. 428) and the indirect (Par. 429) methods respectively are perfectly general; consequently by their use any problem may be solved provided all deviation or precision measures are expressed as actual numerical deviations and not as fractional or percentage deviations. It is found in practice that nearly all formulæ used in indirect measurements fall in one or the other of two general groups. Those of the first class include all those functions which contain sums or differences of terms, each of which may involve either measured components, or constants, or both. The general form would be

$$X = Aa^l \pm Bb^m \pm Cc^n \pm \ldots \tag{68}$$

where $A, B, C \ldots$ are constants and $a, b, c \ldots$ are measured quantities entering to the $l^{th}$, $m^{th}$, and $n^{th}$ powers respectively. Examples of formulæ of this sort are the expressions for the electromotive force of a standard Clark cell, $E = 1.4340\ [1 - 0.00078\ (t° - 15°)]$, or the resistance of a standard 10-ohm coil, $R = 10[1 + 0.00388\ (t° - 15°)]$.

Those of the second class include all those functions which involve products, quotients or powers of the measured components and constants and do not involve either trigonometric or logarithmetic functions. The general type would be

$$X = A \cdot a^l \cdot b^m \cdot c^n \ldots \tag{69}$$

where $A$, $n$, $m$, and $k$ are constants (positive, negative, fractional or integral). An example of formulæ of this type is the expression for the modulus of elasticity for bending, given as $E = Wl^3/4a\,bd^3$, where $W$ is the load at the centre, $l$ is the length between supports, $a$ is the deflection, $b$ the breadth and $d$ the depth of the beam; the formula given above for density (Par. 426) is another example.

**432. Percentage method of computing precision.** Problems of the second class (Par. 431) may be solved much more easily by the fractional or percentage method than by the general method, as will appear from the following. Taking the general form of the function as

$$X = A \cdot a^n \cdot b^m c^k \ldots \tag{70}$$

and differentiating with respect to each of the variables, and then dividing each of these results by the general formula gives,

$$\frac{\Delta a}{X} = \frac{l \cdot \delta a}{a}, \quad \frac{\Delta b}{X} = \frac{m \cdot \delta b}{b}, \quad \frac{\Delta c}{X} = \frac{n \cdot \delta c}{c}. \tag{71}$$

This shows that a fractional deviation $\delta a/a$ in $a$ produces a fractional deviation in $X$ which is $n$ times as great, or in per cent. it means that if $a$ is unreliable by 1 per cent., $X$ will be unreliable $n$ times 1 per cent. and it is to be noted that the remaining factors in the formula have no effect whatever upon this relation. This enables us to state at once the separate effect of any percentage deviation of a given component and by using the relation

$$\frac{\Delta}{X} = \sqrt{\left(\frac{\Delta a}{X}\right)^2 + \left(\frac{\Delta b}{X}\right)^2 + \left(\frac{\Delta c}{X}\right)^2 + \ldots} \tag{72}$$

or its equivalent,

$$\frac{\Delta}{X} = \sqrt{\left(l\frac{\delta a}{a}\right)^2 + \left(m\frac{\delta b}{b}\right)^2 + \left(n\frac{\delta c}{c}\right)^2 + \ldots} \tag{73}$$

we can therefore express the final resultant effect as a percentage deviation.

**433. The percentage method is illustrated by the following problem.** Measurements for the modulus of elasticity using the above formula are as follows. The weight is 10 kg., reliable to the nearest gram; the length is 1,000 mm., reliable to 0.5 mm.; the deflection is 6.983 mm., reliable to 0.007 mm; the breadth is 4.675 mm., reliable to 0.005 mm.; and the depth is 15.069 mm., reliable to 0.008 mm. The problem is to determine the reliability of the modulus when calculated from the formula $E = W \cdot l^3/4\ a.b.d^3$. The first step is to express all the deviations in per cent. Inspection shows that $W$

Digitized by Google

s reliable to 0.01 per cent., $l$ to 0.05 per cent., $a$ to 0.10 per cent., $b$ to 0.10 per cent. and $d$ to 0.05 per cent. and by Eq. 71 we get $100\,\Delta w/E = 0.01$ per cent.; $100\,\Delta l/E = 0.15$ per cent.; $100\,\Delta a/E = 0.1$ per cent.; $100\,\Delta b/E = 0.10$ per cent.; and $100\,\Delta d/E = 0.15$ per cent. Substituting these values in either Eq. 72 or Eq. 73 we get for the percentage reliability of $E$: $100\,\Delta/E = \sqrt{0.01^2 + 0.15^2 + 0.10^2 + 0.10^2 + 0.15^2} = 0.25$ per cent., *i.e.*, the combined effect of all the deviations amounts to 0.25 per cent. in the value of the modulus. Then $E = 22{,}420 \pm 56$ kg. per square millimeter.

**434. The converse problem in the percentage method** would be as follows. It is desired to measure the modulus to 1 per cent.; how precisely must each of the above five components (Par. 433) be measured, and, secondly, can any of them be measured with negligible precision? An inspection of the above measurements, or a knowledge of measurements, would show that the weight might be measured so precisely as to be regarded as a constant, and hence $n = 4$; then we should have, assuming equal effects, $\Delta l/E = \Delta_a/E = \Delta_b/E = \Delta_d/E = \Delta/E\sqrt{4} = 1/100\sqrt{4} = 1/200 = 0.5$ per cent. Applying Eq. 71 we find the percentage deviations to be as follows: $100\,\delta l/l = 0.5/3 = 0.17$ per cent; $100\,\delta_a/a = 0.5$ per cent.; $100\,\delta_b/b = 0.5$ per cent.; $100\,\delta_d/d = 0.5/3 = 0.17$ per cent.

With a little experience one can write the result of either the direct or the converse problem, by the percentage method, from inspection, or at most with a small amount of calculation. It should be noted that the equal-effect method often gives only a first approximation to the best result, for it often is true that one or more components can be measured with negligible precision if equal effects are assumed, in which case a second solution must be made treating such components as constants.

# SECTION 4

## CONDUCTOR MATERIALS

### GENERAL

**1. Conductors and non-conductors.** All materials possess, in some degree, the property of electric conductivity and the question whether a given material shall be classed as a conductor or a non-conductor is entirely one of degree. Certain materials are readily classified in these two general groups; metals, for instance, are easily classed as conductors, whereas such substances as mica, glass, rubber and mineral oil are classed as non-conductors. Certain other materials are not easily classified, because their properties undergo extreme changes with their degrees of purity, treatment and temperature. In general, all materials which are used commercially for conducting electricity can be classed as conductors; and those materials used commercially for obstructing the flow of electricity can be classed as non-conductors, a better term being *insulators* or *dielectrics*. Substances which are neither good conductors nor good insulators can be termed semi-conductors.

**2. Solid conduction,** or the property of conduction through bodies in the solid state, is explained in Sec. 2. This type of conduction is the only one considered at length in this section (Sec. 4).

**3. Liquid conduction,** while it refers mainly to the conduction o **electrolytes** (Sec. 19), also includes liquids of elements in the pure state as distinguished from chemical solutions, acid or basic. The property of liquid conduction is treated at length in Sec. 19, on "Electrochemistry" (also see Sec. 20, on "Batteries").

**4. Gaseous conduction,** or the conducting power of gases, usually in a rarefied state, is also outside the scope of Sec. 4 and is taken up in Sec. 19.

**5. The theory of conduction** is briefly explained in Sec. 2. The electron theory, or modern view of conduction phenomena, is treated more fully in Sec. 22.

**6. Effect of temperature.** The resistivity of all metals becomes greater as the temperature rises. These materials are said to have positive temperature coefficients of resistance. Carbon and electrolytes, on the opposite hand, have negative temperature coefficients; that is, their resistivity becomes less as the temperature rises. There are certain alloys, such as manganin, which have very small temperature coefficients, but such materials form the exception. It has also been found, in the case of copper, that the temperature coefficient of resistance varies directly as the percentage of conductivity with respect to the annealed copper standard (Par. 41).

**7. Temperature coefficient of resistance.** The resistance of any conductor, over at least a limited range, can be expressed by the linear equation,

$$R_t = R_0(1 + \alpha_0 t) \qquad \text{(ohms)} \qquad (1)$$

where $R_t$ is the resistance at any temperature $t$, $R_0$ is the resistance at 0 deg. cent. and $\alpha_0$ is the temperature coefficient per deg. from and at zero deg. At some other reference temperature $t_1$, the resistance is

$$R_t = R_1[1 + \alpha_1(t - t_1)] \qquad \text{(ohms)} \qquad (2)$$

where $R_1$ is the resistance at $t_1$ deg. and $\alpha_1$ is the coefficient from and at the temperature $t_1$ deg. These formulas take no account of the change of di-

Digitized by Google

mensions with change of temperature and therefore apply to the case of conductors of constant mass, usually met in engineering work. For a full discussion of this subject see Dellinger, J. H. "The Temperature Coefficient of Copper," Bulletin of the Bureau of Standards, 1911, Vol. VII, No. 1, p. 71; and "Copper Wire Tables," Circular No. 31, 3rd edition, 1914, Bureau of Standards.

**8. Effect of chemical composition.** The resistivity of most metals is very sensitive to slight changes in chemical composition. Particularly is this true of copper; when alloyed, for example, with 1 per cent. of another metal, its increase in resistivity, measured in per cent., is many times 1 per cent. See Par. **63** and **64**. Therefore it is very essential when stating a value of resistivity for a given substance to state also what the substance is composed of, or if it be so nearly pure that there are no more than small traces of foreign substances, to state its percentage of purity.

**9. Effect of mechanical treatment.** When ductile metals are subjected to cold rolling, drawing, hammering, or to cold working of any kind, they become harder, stronger and slightly more dense. At the same time the resistivity increases, sometimes markedly, and the initial properties can only be approached again by means of the **annealing process.** While this process will sometimes restore the initial properties, at least for most practical purposes, it does not always do so.

## WIRE GAGES

**10. The sizes of wire** have been for many years indicated in commercial practice almost entirely by gage numbers, especially in America and England. This practice is accompanied by some confusion because numerous gages are in common use. The most commonly used gage for electrical wires, in America, is the **American wire gage** described fully in Par. **13**. The most commonly used gage for steel wires is the **steel wire gage** briefly mentioned in Par. **15**.

There is no legal standard wire gage in this country, although a gage for sheets was adopted by Congress in 1893 (see Par. **214**). In England there is a legal standard known as the **standard wire gage**, mentioned in Par. **17**. In Germany, France, Austria, Italy and other continental countries practically no wire gage is used, but wire sizes are specified directly in millimeters. This system is sometimes called the **millimeter wire gage** (see Par. **23**). The wire sizes used in France, however, are based to some extent on the old Paris gage ("jauge de Paris de 1857"). For a history of wire gages see Circular No. 31, "Copper Wire Tables," Bureau of Standards, 3rd Edition, Oct. 1, 1914.

There is a growing tendency to **abandon gage numbers** entirely and specify wire sizes by the **diameter in mils** (thousandths of an inch). This practice holds particularly in writing specifications, and has the great advantages of being both simple and explicit. A number of the wire manufacturers also encourage this practice, and it was definitely adopted by the United States Navy Dept. in 1911.

**11. The mil** is a term universally employed in this country in connection with wire gages and is a **unit of length equal to one thousandth of an inch.**

**12. The circular mil** is another universal used term, being a unit of area equal to the area of a circle 1 mil in diameter. Such a circle, however, has an area of 0.7854 (or $\pi/4$) **sq mil.** Thus a wire 10 mils in diameter has a cross-sectional area of 100 circ. mils or 78.54 sq. mils. Hence, 1 circ. mil equals 0.7854 sq. mil.

**13. The American wire gage,** also known as the **Brown & Sharpe gage,** was devised in 1857 by J. R. Brown. It is usually abbreviated **A. W. G.** This gage has the property, in common with a number of other gages, that its sizes represent approximately the successive steps in the process of wire drawing. Also, like many other gages, its numbers are retrogressive, a larger number denoting a smaller wire, corresponding to the operations of drawing. These gage numbers are not arbitrarily chosen, as in many gages, but follow the mathematical law upon which the gage is founded. The gage numbers and sizes are given in Par. **30**.

Digitized by Google

The theoretically exact diameters in this gage, as given in the second column of Par. **30**, contain more significant figures than there is any commercial need for, and hence the large companies have standardised the sizes given in the third column, using the nearest mil for large sizes and the nearest tenth of a mil for the smaller sizes. These commercial sizes were adopted as standard by the United States War Dept. in 1911.

**14. The basis of the American wire gage** is a simple mathematical law. The gage is formed by the specification of two diameters and the law that a given number of intermediate diameters are formed by geometrical progression. Thus, the diameter of No. 0000 is defined as 0.4600 in. and of No. 36 as 0.0050 in. There are 38 sizes between these two, hence the ratio of any diameter to the diameter of the next greater number is given by this expression

$$\sqrt[39]{\frac{0.4600}{0.0050}} = \sqrt[39]{92} = 1.122\ 932\ 2$$

The square of this ratio = 1.2610. The sixth power of the ratio, *i.e.*, the ratio of any diameter to the diameter of the sixth greater number = 2.0050. The fact that this ratio is so nearly 2 is the basis of numerous useful relations or short cuts in wire computations.

**15. The steel wire gage,** also known originally as the **Washburn & Moen gage** and later as the **American Steel & Wire Co.'s gage,** was established by Ichabod Washburn about 1830. This gage also, with a number of its sizes rounded off to thousandths of an inch, is known as the **Roebling gage.** It is used exclusively for steel wire. The numbers and sizes are given in Par. **30**.

**16. The Birmingham wire gage,** also known as **Stubs' wire gage** and **Stubs' iron wire gage,** is said to have been established early in the eighteenth century in England, where it was long in use. This gage was used to designate the Stubs' soft wire sizes and should not be confused with Stubs' steel wire gage mentioned in Par. **19**. The numbers of the Birmingham gage were based upon the reductions of size made in practice by drawing wire from rolled rod. Thus, a wire rod was called No. 0, first drawing No. 1, and so on. The gradations of size in this gage are not regular, as will appear from its graph. This gage has been used to a considerable extent for designating iron and steel telegraph wires. Its numbers and sizes are given in Par. **30**.

**17. The Standard wire gage,** which more properly should be designated **(British) Standard wire gage,** is the legal standard of Great Britain for all wires, adopted in 1883. It is also known as the **New British Standard gage,** the **English legal standard gage** and the **Imperial wire gage.** It was constructed by so modifying the Birmingham gage that the differences between consecutive sizes became more regular. While this gage is the one most largely used in England, there is a tendency there, as here, to drop gage numbers and specify sizes by the diameter in mils. This gage has never been extensively used in this country. Its numbers and sizes are given in Par. **30**.

**18. The Old English wire gage,** also known as the **London wire gage,** differs very little from the Birmingham gage. It was formerly used to some extent for brass and copper wires, but is now nearly obsolete. The numbers and sizes are given in Par. **30**.

**19. The Stubs' steel wire gage** has a somewhat limited use for tool steel wire and drill rods. It should not be confused with the Birmingham or Stubs' iron wire gage mentioned in Par. **16**. The numbers and sizes are given in Par. **30**. In addition there are twenty-six larger sizes, *Z* to *A*, and thirty smaller sizes, No. 51 to No. 80, besides those given in Par. **30** (see tool catalogue of Brown & Sharpe Mfg. Co., or The L. S. Starrett Co.).

**20. The Trenton Iron Co.'s gage,** of which the numbers and sizes are given in Par. **30**, is used only to a very limited extent. It differs but slightly from the steel wire gage mentioned in Par. **15**.

**21. The French wire gage** is an exception to the other gages given in Par. **30** in the respect that its sizes are progressive, instead of retrogressive, as the numbers advance. The sizes there given were taken from the American Steel and Wire Co.'s handbook, "Electrical Wires and Cables," 1910.

Digitized by Google

**22. The Edison standard wire gage** was proposed some time before 1887 and was based upon the simple principle that the area of cross-section increased proportionately with the gage numbers. Thus No. 5 = 5,000 circ. mils, No. 10 = 10,000 cir. mils, etc. This gage never came into general use.

**23. The Millimeter wire gage,** also known as the **Metric wire gage,** is based on giving progressive numbers to the progressive sizes, calling 0.1 mm. diameter No. 1, 0.2 mm. No. 2, etc.

**24. The German gage,** in which the diameters or thickness are expressed in millimeters, is retrogressive and contains 25 sizes. The gage numbers and sizes are given in Par. **29.**

**25. Large sizes of wire,** above No. 0000 A.W.G., are specified by the total cross-section in **circular mils.** This applies in particular to large cables.

**26. The United States standard sheet gage,** for sheet and plate iron and steel, was adopted by Congress on March 3, 1893 (see 27 Stat. L., 746) and established a uniform legal standard for the United States. The numbers and thicknesses in this gage are given in Par. **30,** for comparison with wire gages. A full table of gage numbers, thicknesses and weights is given in Par. **216.**

**27. The standard decimal gage for sheet metals,** designating the thickness in **mils,** was recommended in 1895 by the Association of American Steel Manufacturers, the American Railway Master Mechanics' Association and the American Society of Mechanical Engineers. There are 38 sizes, ranging from 2 mils to 250 mils. See Par. **216** for a full table of sizes and weights.

**28. The measurement of wire diameters** may be accomplished in three ways, viz., by means of a micrometer caliper, by means of a wire gage such as that shown in Fig. 1, or by means of a V-gage. The most accurate means is a micrometer caliper, which reads directly to mils, and, by estimating tenths of the smallest scale division, to tenths of a mil. The most accurate type of micrometer is one equipped with a miniature friction clutch, which eliminates errors caused by gripping the wire too firmly between the jaws.

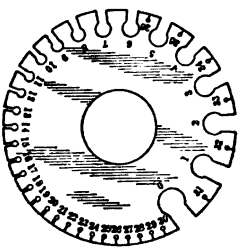

FIG. 1.—Gage for testing the sizes of wires.

## COPPER

**31. General properties.** Copper, which is by far the most important metal in the electrical industry, is a highly malleable and ductile metal, of a reddish color. The density varies slightly, depending on the physical state, an average value being 8.9. Copper melts at 1,083 deg. cent.* (1,981 deg. fahr.), and in the molten state has a sea-green color. When heated to a very high temperature it vaporises, and burns with a characteristic green flame. Copper boils at 2,310 deg. cent. (4,190 deg. fahr.).† Molten copper readily absorbs oxygen, hydrogen, carbon monoxide and sulphur dioxide; on cooling, the occluded gases are liberated, tending to give rise to blow holes and porous castings. The presence of lead in molten copper tends to drive off both carbon dioxide and water vapor.

Copper when exposed to ordinary air becomes oxidised, turning to a black color, but the coating is protective and the oxidising process is not progressive as with iron and steel. When exposed however to moist air containing carbon dioxide, it becomes coated with green basic carbonate. It is also affected by sulphur dioxide. It resists the action of hydrochloric, sulphuric and strong nitric acids, at ordinary temperatures, but is acted upon by dilute nitric acid.

The electrical conductivity of copper depends most critically on its degree of chemical purity (see Par. **33**) and also, in much less degree, upon the physical state, being reduced slightly (from 2 per cent. to 4 per cent.) by cold rolling and drawing. The tensile properties depend greatly upon the physical state, being much improved by cold rolling and drawing.

The alloys of copper are exceedingly numerous, both for electrical and mechanical purposes. Among the most important for electrical purposes are German or nickel silver, bronze and brass. Copper solders readily with ordinary low-temperature solders; solder alloys with copper at about 238 deg. cent. (460 deg. fahr.).

**32. Commercial grades of copper.** In the copper trade there are three recognized grades of copper known as **electrolytic, Lake,** and **casting.**‡ The first, electrolytic, is that refined by the electrolytic method and is highly pure (see Par. **34**). The second, Lake, is also highly pure, in its natural or mineral state, and requires simply to be melted down to bars, for convenient handling (see Par. **36**). The third kind of copper, known as casting copper, contains more impurities and consequently runs lower in conductivity. It is, as its name implies, more suitable for mechanical than electrical applications (Par. **35**).

**33. Density of copper.** The internationally accepted density of annealed copper,§ expressed in grams per cu. cm. at 20 deg. cent., is **8.89**; this of course is also the specific gravity at 20 deg. cent., referred to water at 4 deg. cent. The American Society for Testing Materials has accepted this value, on account of its international endorsement, but considers that a value of 8.90 is probably nearer the exact truth. A density of 8.89 at 20 deg. cent. corresponds to 8.90 at 0 deg. cent. In English units the international standard equals 0.32117 lb. per cu. in. Also see "Copper Wire Tables," circular No. 31, Bureau of Standards, Washington, D. C.; and "Smithsonian Physical Tables," Washington, D. C., 1910, 5th rev. ed., p. 85.

**34. Electrolytic copper.** The electrolytic refinement of copper‖ (see Sec. 19) not only produces metal of the highest purity, but it is eco-

Digitized by Google

nomically necessary when precious metals are present in the ore. This grade of copper should run higher than 99.88 per cent. of pure metal. An analysis of average electrolytic copper, representing neither the best nor the worst, was furnished by Mr. Lawrence Addicks and appears in Par. **35**. The minute quantities of impurities there shown of course fluctuate from time to time in any given refinery, and there are usually certain typical differences among the refineries, owing to individual characteristics of the bullion supply. Wire bars of electrolytic copper are made by melting down the cathode copper in a furnace and casting in the desired form and size.

**35. Average analysis of commercial electrolytic copper**

(L. Addicks)

| Conductivity 100 per cent. | | | |
|---|---|---|---|
| Element | Per cent. | Element | Per cent. |
| Copper | 99.93 | Tellurium | 0.0006 |
| Sulphur | 0.0010 | Selenium | 0.0003 |
| Nickel | 0.004 | Iron | 0.0030 |
| Lead | 0.0008 | Aluminum | 0.0020 |
| Arsenic | 0.0018 | Phosphorus | 0.0004 |
| Antimony | 0.0030 | Silver | (1) |
| Bismuth | 0.0002 | Gold | (2) |

(1) 0.4 oz. per ton.
(2) 0.005 oz. per ton.

**36. Lake copper** is the grade of material which comes from the northern Michigan (U. S. A.) peninsular, being the only known variety which occurs in nature with the purity of electrolytically refined metal. The rock ore containing the metal is crushed in stamp mills, concentrated and melted, requiring no further treatment than "poling" (introducing sticks of green hardwood into the metal) to reduce the oxides and bring it to tough pitch.

Some of the Lake copper coming from the deeper ore deposits has been found to contain appreciable quantities of arsenic, which is very injurious to electrical conductivity.* Where the quantity of arsenic is high enough to injure the conductivity appreciably, the metal is either sold as arsenical copper or else refined electrolytically.

**37. Specifications for electrolytic and Lake Copper wire bars** have been adopted by the American Society for Testing Materials. See the current "Year Book" of the society, for full details.

**38. Casting copper** is more or less impure copper, too low in conductivity for electrical uses, but entirely suitable for most other applications. There are three sources of this grade of copper: (1) fire-refined copper from virgin sources; (2) copper electrolytically produced by deposition from impure liquors; (3) and copper reclaimed from secondary sources. The copper contents of the better known brands of casting copper run in general over 99 per cent., but some will run less. It is, as its name implies, exclusively a foundry copper.

**39. Standards of resistivity.** The table in Par. **40** presents a summary of the standards of resistivity, temperature coefficient and resistivity which have been most in use. The particular standard temperature in each column is indicated by enclosure in parentheses ( ), and the other values are computed from the standard temperature. A full discussion of these values will be found in "Copper Wire Tables," Circular No. 31, Bureau of Standards, pp. 5 to 10. The latest accepted value of resistivity is the **"International Annealed Copper Standard,"** given in column 8; all tables given in this section for annealed copper wire are based on this standard, which is covered more specifically in Par. **41**.

**41. The International Annealed Copper Standard** is the internationally accepted value* for the resistivity of annealed copper of 100 per cent. conductivity. This standard is expressed in terms of mass-resistivity as **0.15328 ohm (meter, gram)**, or the resistance of a uniform round wire 1 m. long weighing 1 gram, at the standard temperature of **20 deg. cent.** Equivalent expressions of the annealed copper standard, in various units of mass resistivity and volume resistivity, are as follows:

| | | |
|---|---|---|
| 0.15328 | ohm (meter, gram) | at 20 deg. cent. |
| 875.20 | ohms (mile, lb.) | |
| 1.7241 | microhm-cm. | |
| 0.67879 | microhm-in. | |
| 10.371 | ohms (mil, ft.) | |
| 0.017241 | ohm (meter, mm.²) | |

It may be convenient to note that a value of 0.017241 ohm (meter, mm.²) is exactly $\frac{1}{58}$ ohm, so that the volume conductivity at 20 deg. cent. can be expressed 58 mho (meter, mm.²).

It is important to observe that weight-measure rather than volume-measure is commercially the more important in wire calculations, since wire is sold by the pound. Therefore the most attention should be given to mass-resistivity and mass resistance.

**42. Temperature coefficient of mass resistance.** This coefficient, which applies to resistance calculations when a conductor is defined in terms of its mass, is the one commonly employed in engineering calculations; that is to say, in common practice, the mass of a conductor remains the same at all temperatures, and changes of volume, length, or sag are disregarded. It is important to note that it does not apply to a conductor defined in terms of its volume.

The temperature coefficient (for constant mass) of the annealed copper standard, 100 per cent. conductivity, is 0.00393 per deg. cent., at 20 deg. cent. The coefficient changes with the temperature of reference, as given in Par. **40**, column 8.

**The coefficients for copper of less than standard** (or 100 per cent.) **conductivity** is proportional to the actual conductivity, expressed as a decimal percentage. Thus if $n$ is the percentage conductivity (95 per cent. = 0.95), the temperature coefficient will be $\alpha'_t = n\alpha_t$, where $\alpha_t$ is the coefficient of the annealed copper standard.

The coefficients given in the table in Par. **43** were computed from the formula

$$\alpha_t = \frac{1}{\frac{1}{n(0.00393)} + (t_1 - 20)} \qquad (3)$$

The quantity $-T$ given in the last column (Par. **43**) is the inferred absolute zero of temperature, assuming a linear relationship between resistance and temperature. At the absolute zero of temperature the resistance would be zero.

**43. Table of temperature coefficients of copper for different initial temperatures (centigrade) and different conductivities**

| Ohms (meter, gram) at 20 deg. cent. | Per cent. conductivity | $\alpha_0$ | $\alpha_{20}$ | $\alpha_{25}$ | $-T$, "Inferred absolute zero" |
|---|---|---|---|---|---|
| 0.16134 | 95 | 0.00403 | 0.00373 | 0.00367 | −247.8 |

**44. Reduction of observations to standard temperature.** A table of convenient corrections and factors for reducing resistivity and resistance to standard temperature, 20 deg. cent., will be found in "Copper Wire Tables," Circular No. 31, Bureau of Standards.

**45. Calculation of per cent. conductivity.** The per cent. conductivity of a sample of copper is calculated by dividing the resistivity of the International Annealed Copper Standard at 20 deg. cent. by the resistivity of the sample at 20 deg. cent. Either the mass resistivity or volume resistivity may be used. Inasmuch as the temperature coefficient of copper varies with the conductivity, it is to be noted that a different value will be found if the resistivity at some other temperature is used. This difference is of practical moment in some cases. In order that such differences shall not arise, it is best always to use the 20 deg. cent. value of resistivity in computing the per cent. conductivity of copper. When the resistivity of the sample is known at some other temperature, $t$, it is very simply reduced to 20 deg. cent. by adding the quantity $(20-t)$ multiplied by the "resistivity-temperature constant," given in Par. **46.**

**46. Resistivity-temperature constant.** The *change of resistivity per degree* may be readily calculated, taking account of the expansion of the metal with rise of temperature. The proportional relation between temperature coefficient and conductivity may be put in the following convenient form for reducing *resistivity* from one temperature to another: *The change of resistivity of copper per degree cent. is a constant, independent of the temperature of reference and of the sample of copper. This "resistivity-temperature constant" may be taken, for general purposes, as* 0.00060 *ohm (meter, gram), or* 0.0068 *microhm-cm.* For further details, see "Copper Wire Tables," Circular No 31, Bureau of Standards, Washington, D. C.

**47. Complete copper-wire tables,** based on the International Annealed Copper Standard, are given in Par. **50,** and represent approximately an average of the present commercial conductivity of copper. For annealed wires, the resistivity is independent of the size. These tables are reproduced directly from Circular No. 31, 3rd Edition, issued by the Bureau of Standards. The quantities were computed to five significant figures and rounded off to the fourth place, being therefore correct within 1 in the fourth significant figure. The volume resistivity at 20 deg. cent., used in calculating these tables, was 0.67879 microhm-in. and the density, 8.89 at 20 deg. cent. or 0.321,17 lb. per cu. in. The tables in Circular No. 31 contain additional columns for 0 deg., 15 deg., 25 deg. and 75 deg. cent. What the tables show is the resistance at various temperatures, of a wire which at 20 deg. cent. is 1,000 ft. long and has the specified diameter, and which varies in length and diameter at other temperatures.

**48. Explanatory notes on copper wire tables.**

NOTE 1.—The *fundamental resistivity* used in calculating the tables is the International Annealed Copper Standard, viz., 0.15328 ohm (meter, gram) at 20 deg. cent. The *temperature coefficient* for this particular resistivity is $\alpha_{20} = 0.00393$, or $\alpha_0 = 0.00427$. However, the temperature coefficient is proportional to the conductivity, and hence the change of *resistivity* per deg. cent. is a constant, 0.000597 ohm (meter, gram). The "constant mass" temperature coefficient of any sample is

$$\alpha_t = \frac{0.000597 + 0.000005}{\text{resistivity in ohms (meter, gram) at } t \text{ deg. cent.}} \qquad (4$$

The *density* is 8.89 g. per cu. cm.

NOTE 2.—The values given in the tables are only for annealed copper of the standard resistivity. The user of the table must apply the proper correction for copper of any other resistivity. Hard-drawn copper may be taken as about 2.7 per cent. higher resistivity than annealed copper.

NOTE 3.—This table is intended as an ultimate reference table, and is computed to a greater precision than is desired in practice. The practical user of a wire table is referred to the "Working Tables," Par. **51.**

**49. Working copper-wire tables,** based on the International Annealed Copper Standard, are given in Par. **51.** This table is carried only to three significant figures, and is more convenient for most practical work. The table itself is adapted from Circular No. 31, 3d edition, issued by the Bureau of Standards, and amplified by the addition of values based on the mile unit.

This table is correct to three significant figures, only.

Digitized by Google

**52. Reference to copper-wire tables in other gages.** For copper-wire tables in the British Standard Wire Gage and in the Millimeter Gage, based on the International Annealed Copper Standard, see Bulletin No. 31, 3d edition (Oct. 1, 1914), issued by the Bureau of Standards.

**53. Conductivity of hard-drawn copper.** The conductivity of hard-drawn copper, expressed as a percentage of the conductivity of the annealed copper standard, varies with the size of wire, becoming smaller as the wire becomes smaller. It is impracticable, however, to state any general rule, because of differences in manufacturing practice, as to the number of drawings between annealings, amount of reduction to each drawing, etc. The Bureau of Standards found that the conductivity of No. 12. A.W.G. hard-drawn copper was 97.3 per cent. The copper-wire specifications of the American Society for Testing Materials, call for resistivities which correspond to the following percentage conductivities, based on the annealed copper standard.

| | Per cent., conductivity |
|---|---|
| Annealed copper | 98.2 |
| Medium-hard drawn, above 0.325 in | 97.7 |
| Medium-hard drawn, below 0.325 in | 96.7 |
| Hard-drawn, above 0.325 in | 97.2 |
| Hard-drawn, below 0.325 in | 96.2 |

The density of all these grades of wire is taken as the same, or 8.89 at 20 deg. cent.

**54. Temperature coefficient of expansion.** The temperature coefficient of linear expansion of copper is approximately 0.000017 per deg. cent. The values given in the "Tables Annuelles de Constantes et Donnés Numériques," for 1910, are as follows (p. 44 and p. 45): Between − 190 deg. and 17 deg. cent., 0.00001418; between 17 deg. and 100 deg. cent., 0.00001636; and by Stéphan's determinations (1910).

$$l_t = l_0[1 + 0.00001607t + 0.000000000403t^2] \qquad (5)$$

Matthiessen's mean coefficient* between 0 deg. and 100 deg. cent., was 0.00001666 and Fizeau found the value* at 40 deg. cent. to be 0.00001678. By computation from Stéphan's results the mean coefficient between 0 deg. and 100 deg. cent. is 0.0000165. The mean of these four results is 0.0000166 per deg. cent. The corresponding value in the fahrenheit scale is 0.00000922 per deg.

**55. Concentric strand, or cable,** is a conductor made up of a straight central wire (or group of wires) surrounded by helical layers of bare wires (or groups of wires), the alternate layers having a twist in opposite directions. The term "concentric-lay" applies when the strands are composed of single bare wires; the term "rope-lay" applies when the strands are made up of groups of wires, each group in concentric lay. All the individual strands are of the same size. If there are $n$ layers over the core of a concentric-lay cable, not counting the core as a layer, the **total number of strands** or wires will be

$$N = 3n(n+1) + 1 \qquad (6)$$

**The diameter** of such a cable is the diameter of the circumscribing circle, or

$$D = d(2n+1) \qquad (7)$$

where $d$ is the diameter of any strand or individual wire. In a rope-lay cable, such as some forms of extra flexible cable, where instead of individual single wires there are groups of wires, each group consisting of a concentric-lay cable, the total number of wires $N$ in the entire cable will be that given by Eq. 6 for concentric-lay cable multiplied by the number of wires in each component group. Thus a rope-lay cable comprising 1 layer, with 7 wires in each group, would have $7 \times 7 = 49$ wires, and is sometimes called a $7 \times 7$ rope. Such an expression as a $19 \times 7$ rope strand means 19 strands, each composed of 7 wires. A $7 \times 7$ rope strand is not economical for large conductors and is usually confined to sizes like No. 4 A.W.G. or smaller. For large sizes a $19 \times 7$ or $37 \times 7$ rope strand is more compact and presents a smoother exterior.

**The number of circular mils** in a cable composed of $N$ wires is

$$C.M. = Nd^2 \qquad (8$$

where $d$ is the diameter of each wire in mils (thousandths of an inch).

**The equivalent solid conductor** is one having the same number c circular mils, or its diameter is

$$D' = \sqrt{Nd^2} \qquad (9$$

It is *not* equal to the normal cross-section of the cable, because in the las case the strands are cut at a slight angle (due to their pitch) and such section is therefore larger than the true section, equal to the sum of the norma sections of all the strands, each taken normal to its own axis.

**The ratio of the diameter** of concentric strand to the diameter o equivalent solid conductor is given by

$$\frac{D}{D'} = \frac{2n+1}{\sqrt{N}} = \sqrt{\frac{4n^2+4n+1}{3n^2+3n+1}} \qquad (10$$

Substitution in this formula from $n=0$ to $n=8$, gives the following value of the ratio.

| $n$ | $N$ | $\frac{D}{D'}$ | $n$ | $N$ | $\frac{D}{D'}$ | $n$ | $N$ | $\frac{D}{D'}$ |
|---|---|---|---|---|---|---|---|---|
| 0 | 1 | 1.000 | 3 | 37 | 1.151 | 6 | 127 | 1.154 |
| 1 | 7 | 1.134 | 4 | 61 | 1.152 | 7 | 169 | 1.154 |
| 2 | 19 | 1.147 | 5 | 91 | 1.153 | 8 | 217 | 1.154 |

This shows that the larger the number of strands, for a given cross-section the larger will be the outside diameter, approaching, however, a limiting ratio of 1.154. Therefore the size and the cost of a conductor of given cross-section increase as the number of strands increases.

**The individual wires** of a cable can seldom be drawn to any of the standard gage numbers, because the diameter of the wire is fixed by the required size of the cable, and the number of wires composing it. Also see "Wire In Electrical Construction," John A. Roebling's Sons Co., 1906; and "Electrical Wires and Cables," Amer. Steel & Wire Co., 1910.

**56. Composition of standard concentric strands***

| Range of size | Number of wires | |
|---|---|---|
| | Standard concentric strands | Flexible concentric strands |
| 2,000,000 to 1,600,000 cir. mils | 127 | 169 |
| 1,500,000 to 1,100,000 cir. mils | 91 | 127 |
| 1,000,000 to 550,000 cir. mils | 61 | 91 |
| 500,000 to 250,000 cir. mils | 37 | 61 |
| No. 0000 to No. 1 A.W.G. | 19 | 37 |
| No. 2 to No. 8 A.W.G. | 7 | 19 |

**57. Pitch or lay of concentric strand.** The axial length of one complete turn of any individual strand in a concentric-lay cable, divided by the diameter of the cable, is called the pitch or lay. The **pitch angle** of the cable is shown in Fig. 2, where $ac$ represents the axis of the cable and $l$ is the axial length of one complete twist; $ab$ is the length of any individual strand, $l + \Delta l$, in one complete twist; and the angle $bac$, or $\theta$, is the pitch angle. The side $bc$ is equal to the circumference of the circle circumscribing the cable. In this case the pitch $p$ is given by $p = l/d$. There is no fixed

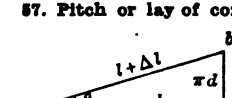

FIG. 2.—Pitch angle in concentric lay cable.

* See Circular No. 37, "Electric Wire and Cable Terminology;" Bureau of Standards; 2nd ed., Jan. 1, 1915, page 13: A. I. E. E. Standardization Rules, 1914; also see latest edition of Standardization Rules, Sec. 24.

Digitized by Google

standard pitch used by all cable manufacturers. Also see "Electrical Wires and Cables," Amer. Steel & Wire Co., 1910, pp. 27 to 35.

**58. Increase in mass and resistance due to stranding.** The Bureau of Standards has shown in Circular 31 (3rd Edition, 1914, p. 71) that the per cent. increase of resistance of a cable with all the wires perfectly insulated from one another, over the resistance of the "equivalent solid rod," is exactly equal to the per cent. decrease of resistance of a cable in which each wire makes perfect contact with a neighboring wire at all points of its surface. That is, if $R_s$ is the resistance of the equivalent solid rod or wire, $R_1$ is the resistance of the cable with perfectly insulated wires and $R_2$ is the resistance of the cable in which all the wires make perfect contact with their neighbors, then $R_s = \frac{1}{2}(R_1 + R_2)$. In general, $R_1 > R_s > R_2$. The resistance of a cable is generally somewhat less than $R_1$, which is shown by the fact that the actual resistance of a cable increases slightly with age, probably due to the formation of oxide on the contact surfaces.

**59. Copper cable tables.** The table in Par. **62** gives the properties of bare concentric-lay copper cables, based on the **International annealed copper standard** (see Par. 41). The column headed "Diameter of Wires" was calculated in each case from the total cross-section. The values given for "ohms per 1,000 ft." and "lb. per 1,000 ft." are 2 *per cent. greater* than for a solid rod of cross-section equal to the total cross-section of the wires of the cable. This increment of 2 per cent. means that the values are correct for cables having a pitch of 15.7. If the pitch is different, the resistance and the mass may be calculated by multiplying the values in the table by the factor

$$1 + \left(\frac{493}{p^2} - 2\right)10^{-2} \qquad (11)$$

For example, if the pitch is 12, the resistance and the mass given in the table should be increased 1.4 per cent.; if the pitch is 30, the values should be decreased 1.5 per cent.

**60. Hemp-centre cables.** If the core of a concentric strand is replaced by hemp, the characteristics of the cable are altered in several respects. The diameter of the cable, for a given cross-section, is greater than the diameter of an all-metal cable; the flexibility is slightly greater, for the same size, being more marked in the case of 7 wires than a greater number; and the skin effect, for equal sizes, is slightly diminished. The tensile strength of a hemp-centre cable would be computed on the basis of the cross-section of metal, disregarding the hemp. Such cables are not in general manufactured in standard sizes, but made up to order. See article by D. B. Rushmore in *General Electric Review*, June, 1912, discussing objections to cables of this type.

**61. Weight of hemp-centre, concentric-lay, copper cable*.**

Made of six wires around a hemp centre
(The American Brass Co.)

| Size of cable, A.W.G. | Made of | Size of each wire (in.) | Outside diameter (in.) | Approximate weight (lb). | |
|---|---|---|---|---|---|
| | | | | Per 1,000 ft. | Per mile |
| No. 0000 | 6 wires | 0.1879 | 0.564 | 673 | 3,553 |
| No. 000 | 6 " | 0.1672 | 0.502 | 551 | 2,909 |

**63. Effect of impurities on the conductivity of copper.** It is well known that the conductivity of copper is highly sensitive to slight impurities. A series of progressive tests on the effect of the presence of very small quantities of foreign elements, with respect to electrical conductivity, was made by Mr. Lawrence Addicks. In order to obtain a comparative figure, Mr. Addicks divided the percentage decrease of conductivity by the percentage of impurity added, and obtained the results given in Par. **64**, which are strictly true only for an infinitely small lowering of conductivity. The factor is seen to bear a general relation to the periodic arrangement, becoming smaller with increasing atomic weight within any one group, though there is no evident relation between one group and another. This factor is of use when examining the analysis of a copper which shows low conductivity, as a means of indicating the probable cause of the trouble. Commercial copper when examined under a microscope reveals a structure made up of grains of pure copper enclosed in matrices of impurities, thus forming a complicated chain of two substances. By adding certain impurities the conductivity of the impure portion of the chain may be increased without changing that of the copper itself, thus showing an increase in the total conductivity of the chain.

**64. Relation between percentage impurity and percentage change in conductivity**

$$\text{* Factor} = \frac{\text{Percentage decrease of conductivity}}{\text{Percentage of impurity added}}.$$

** This value is probably too high and later results indicate an average value of about 600.

**65. Tensile strength.** The mechanical properties of copper extend over a considerable range, depending on its state of hardness. The tensile strength of **annealed copper wire** ranges from about 32,000 lb. or 34,000 lb. per sq. in., in the larger sizes, to as high as 40,000 lb. per sq. in. in the smaller sizes; a very fair assumption is 34,000 lb. as a representative value.

The process of cold drawing increases the strength quite rapidly. So-called **medium hard**, or half hard, copper wire has a tensile strength in the larger sizes ranging from 40,000 lb. to 50,000 lb. per sq. in., and in the smaller sizes from 50,000 lb. to 60,000 lb. per sq. in.

**Hard-drawn wire** has a tensile strength ranging from 50,000 lb. per sq. in. in the large sizes to about 65,000 lb. per sq. in. in the small sizes, or 68,000 lb. in the very small sizes.

Fig. 3 shows the results obtained by Addicks† in making a determination

of the relationship between **tensile strength and conductivity** of copper wire. This shows, among other things, that the properties of copper, after it has been through a cycle of hard drawing and annealing, are not completely restored, but nearly so.

**Concentric strand** or cable should have a total strength equal at least to 90 per cent. of the strength of its component strands. The ultimate strength, however, is theoretically a function of the pitch, and in addition the internal stresses in a cable under load are very complex, so that a factor of 90 per cent. is approximate.

**Cast copper** ranges in tensile strength from 20,000 lb. to 30,000 lb. per sq. in. and has a crushing strength of about 40,000 lb. per sq. in.

**The tinning process,** applied to copper wires which are intended to receive any kind of insulation containing rubber as an ingredient, removes some of the temper of hard-drawn wire and hence impairs its tensile strength. Also see tables of tensile strength in A.S.T.M. specifications for copper wire, current issue of "Year Book."

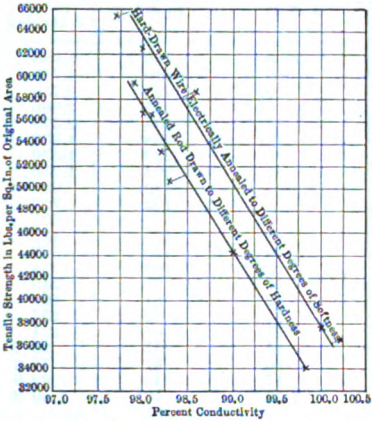

FIG. 3.—Relationship between conductivity and tensile strength in copper wire (Addicks).

**66. Elongation and fracture.** Annealed copper is very ductile and has an ultimate elongation of 35 per cent. to 40 per cent. in the large sizes of wire; in the smaller sizes the elongation decreases to a value of 20 per cent. to 25 per cent. The elongation of medium hard and of hard-drawn wire ranges from 4 per cent. in the largest size to about 1 per cent. in the smallest. The fracture of cast copper is granular and irregular, while that of forged, rolled, or drawn copper is fibrous, with a silky luster. At fracture there is considerable reduction of area, with drawn copper, in the plane of rupture.

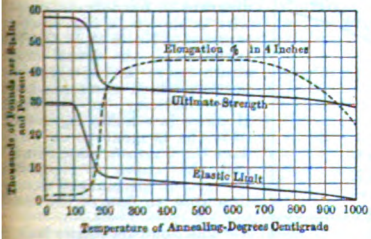

FIG. 4.—Mechanical properties of electrolyte copper as affected by temperature (Hoffman).

**67. The effect of annealing temperature on tensile properties** of copper is illustrated in Fig. 4. See Hoffman, H. O. "Metallurgy of Copper;" New York, McGraw-Hill Book Co., Inc., 1914, page 5.

**68. Effect of impurities on tensile strength.** One of the most common impurities in copper is oxygen, in the form of suboxid of copper ($Cu_2O$). While minute quantities are not harmful, an excess is the cause of brittleness. The presence of lead makes the metal "red short," or "hot short." The presence of bismuth or tellurium makes the metal both "red short" and "cold short."

under stress, being the difference between *ab* and *ae*. The test length was 30 in. and the elongation at rupture was 1.3 per cent. The true elastic limit was 27,000 lb. per sq. in. or 44 per cent. (rather low, below average) of the ultimate tensile strength; Johnson elastic limit, 44,000lb. per sq. in. or 72 per cent. of the ultimate; ultimate tensile strength, 61,400 lb. per sq. in.; modulus (Young's) of elasticity, 17,500,000.

A series of stress-strain curves on annealed, half-hard, and hard copper wires was published in 1904 by Mr. F. O. Blackwell in a paper entitled "Conductors for Long Spans," Trans. International Elec. Cong., St. Louis, 1904, Vol. II, p. 331.

Fig. 6 shows a stress-strain diagram, from Mr. Blackwell's paper, for hemp-centre, hard-drawn, concentric-lay, copper cable composed of six 0.168-in. strands. The curve *A* is for the cable, and *B* for one of the strands. The elastic behavior is notably different from that of solid wire, since the actual elongation of a new or previously unstressed cable appears to comprise two components, one due to tightening or readjustment of the outer strands around the core, and the other to actual stretching of the material.

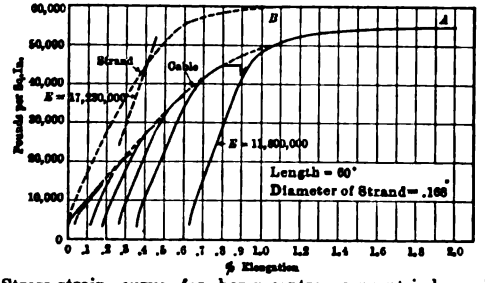

FIG. 6.—Stress-strain curve for hemp-centre, concentric-lay, six-strand, hard-drawn copper cable.

**71. Elastic limit and yield point.** The stress-strain curves for annealed copper show that it has no very definite elastic limit and in fact commences to set (flow under stress) at comparatively low stresses; it also has no yield point, *i.e.*, a point at which a marked increase in elongation suddenly takes place with little or no increase in load. Copper of medium or of full hardness behaves differently and exhibits a fairly definite elastic limit, but no yield point.

The rate of application of the load also plays an important part in the results. When given sufficient time, hard copper takes a set before it reaches the elastic limit. In the strictest meaning of the term, copper probably has no absolutely definite elastic limit whatever. What is ordinarily meant by elastic limit is the value obtained in tests made in a specified manner and at a definite rate of loading, such as outlined by the American Society for Testing Materials. The stress-strain curves also show very plainly that the ultimate elastic limit is raised by stressing the material beyond the initial elastic limit, or giving it a set.

Since annealed copper wire receives some hardening by handling, and also by stressing under ordinary safe loads, it is customary to assume that it has a fairly high elastic limit, one of the accepted values being as high as 85 per cent. of the ultimate strength.* Accepted values for half-hard and full-hard copper range from 50 per cent. to 65 per cent. of the ultimate, being higher for wires which have had the most drawing. A conservative value for copper of all degrees of hardness is 50 per cent. to 55 per cent., never exceeding 60 per cent. as a maximum for small wires which have had many reductions in drawing.

* Report of Committee on Overhead Line Construction, N. E. L. A., 1911; p. 173 (Appendix A).

Digitized by Google

**72. Fatigue under load.** Under long-sustained loads approaching the normal tensile strength, copper has somewhat less strength than the values obtained by ordinary test. Mr. F. O. Blackwell, in the paper referred to in Par. **70**, found that a 0.168-in. hard-drawn wire stressed to 54,000 lb. per sq. in., stretched continuously, and broke in 7 days, 8 hours; pieces of the same wire afterward broke at 61,000 lb. in the testing machine. He concluded that a hard-drawn wire would stand continuously a stress of about 80 per cent. of its normal tensile strength.

**73. Young's modulus of elasticity** for annealed and hard copper is not a very definitely known quantity and the values given for it fluctuate over a considerable range. This may be accounted for, in the case of annealed copper, by the lack of any very definite elastic limit, and the fact that the initial stress-strain diagram departs at a very early stage from Hooke's law; and as soon as a slight load has been applied the properties commence to change. The same difficulties are present, in less degree, in the case of hard-drawn copper. In all cases, the final value of the modulus, after stressing, is almost invariably greater than the initial modulus. The following values represent the extreme range, and a probable average, drawn from several authorities,* expressed in in-lb. measure.

| State | Range | Probable average |
|---|---|---|
| Annealed wire | $7\times10^6$ to $17\times10^6$ | $12\times10^6$ |
| Annealed concentric strand | $5\times10^6$ to $12\times10^6$ | $9\times10^6$ |
| Hard-drawn wire | $13\times10^6$ to $19\times10^6$ | $16\times10^6$ |
| Hard-drawn concentric strand | $10\times10^6$ to $14\times10^6$ | $12\times10^6$ |

**74. Specific heat** of copper is not independent of temperature. The following values were taken from "Tables Annuelles de Constantes et Données Numériques de Chemie, de Physique et de Technologie" (For 1910; University of Chicago Press, 1912), p. 50.

| | |
|---|---|
| Specific heat, at −50 deg. cent | 0.0862 |
| Specific heat, at 0 deg. cent | 0.0910 |
| Specific heat, at +50 deg. cent | 0.0928 |
| Specific heat, from 2.4 to 21.6 deg. cent | 0.09155 |
| Specific heat, from 17 to 100 deg. cent | 0.0925 |

The Bureau of Standards gives, for the range from 15 to 50 deg. cent., the expression $0.0917+0.000048\ (t-25)$; this is in terms of water at 20 deg. cent. For values at high temperatures see Hoffman, H. O. "Metallurgy of Copper;" p. 7.

**75. Thermal conductivity** of copper is a function of temperature, as expressed in the formula $\lambda_t = \lambda_0 (1 + \alpha t)$. The following values of thermal conductivity, in g-cal. (cm-cube) per sec. per deg. cent. were determined by Lorens.†

| | |
|---|---|
| Thermal conductivity, at 0 deg. cent | 0.7189 |
| Thermal conductivity, at 100 deg. cent | 0.7226 |
| Temperature coefficient, from and at 0 deg. cent | 0.000051 |

Hoffman states the thermal conductivity as 0.72 g-cal. (cm-cube) per deg. cent.; Langmuir gives 0.84 g-cal. for commercial copper and 0.92 g-cal. for pure copper.

**76. Properties of copper at very high temperatures.** See a paper by Carl Hering, "The Proportioning of Electrodes for Furnaces," *Trans.* A. I. E. E., Vol. XXIX (1910), pp. 485 to 545. Also covers carbon, graphite and iron.

and will be found in the current issue of the "Year Book." They are too extended for reproduction.

**78. Standard sections for copper trolley wire** are prescribed in the specifications of the A. S. T. M. (see "Year Book") and are shown in Figs. 7 and 8. These sections are known respectively as "grooved" and "figure eight." Copper trolley wires are always hard drawn, in order to secure maximum hardness and strength.

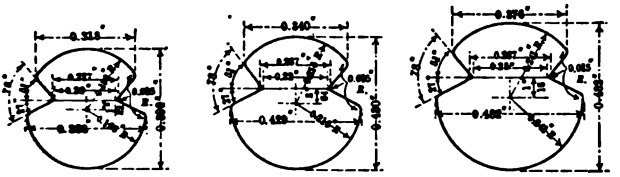

Fig. 7.—"American Standard" grooved trolley-wire sections.

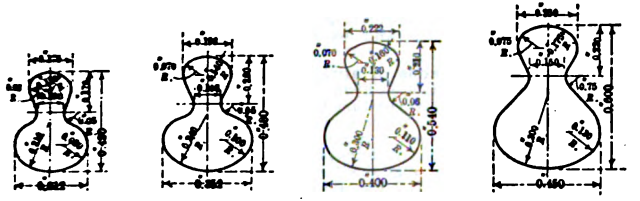

FIG. 8.—Cross-sections of figure-eight trolley wires.

## ALUMINUM

**79. General properties.** Aluminum ranks second to copper in its importance as an electrical conductor, and in some respects is superior to copper. It is one of the softest and most malleable of metals, and is nearly white, or silver-white, in color. The density depends to some extent upon the physical state, an average value being 2.7. Aluminum melts at 658 deg. cent.* (1,216 deg. fahr.). Molten aluminum is very fluid and care should be taken not to overheat it. In the molten state it readily absorbs gases, but upon cooling these occluded gases are partially liberated, giving rise to blow holes in castings. Aluminum boils at 1,800 deg. cent. (3,272 deg. fahr.).†

Like copper, aluminum can be cast, forged, rolled or drawn, and also becomes hardened by working, although it requires less annealing than copper or brass. By cold rolling and drawing it can be given considerable rigidity and temper, with accompanying increase in tensile strength. The general effect of cold or hard drawing upon aluminum is quite similar to the effect upon copper.

Aluminum when exposed to dry air is not affected, but in the presence of moist air it tarnishes rapidly, the coating consisting of oxide of aluminum ($Al_2O_3$) or alumina. This coating is protective, so that the corrosion is not progressive; the oxide is also very refractory, which accounts for the difficulty of soldering aluminum. Hydrochloric acid and alkaline solutions readily attack aluminum; concentrated sulphuric acid, hot dilute sulphuric acid, and hot nitric acid affect it to a less extent. Sulphur and sulphur

Digitized by Google

dioxide do not affect it at ordinary temperatures; it is not attacked by sulphuretted hydrogen, or carbonic acid. It resists the action of sea water better than copper, provided there is no electrolysis, but it is a highly electropositive metal. The presence of impurities in considerable quantities lowers the resistance to corrosion in marked degree. There is also danger from electrolytic corrosion if aluminum is alloyed with an electronegative metal.

The electrical conductivity of aluminum, like that of copper, depends on its degree of chemical purity. The conductivity of hard-drawn aluminum is about 2 per cent. less than that of soft or annealed aluminum. The tensile properties, in like manner, depend greatly upon the physical state, being much improved by cold rolling and drawing.

The alloys of aluminum are very numerous. The so-called light alloys, containing but small percentages of other metals, are light, hard and strong, but do not resist corrosion from galvanic action. The heavy alloys, or aluminum-bronzes, with but 2 per cent. to 10 per cent. of aluminum, and respectively 98 per cent. to 90 per cent. of copper, have high tensile strength and strongly resist corrosion in air or sea water. A very small proportion of aluminum, about 0.01 per cent., added to iron, steel or brass in casting removes the oxide and prevents blow holes.

The tinning process, which is applied to copper wires intended to receive an insulation of rubber compound (sulphur being present), is unnecessary in the case of aluminum.

Aluminum possesses an insulating film which ordinarily has a dielectric strength of about 0.5 volt, and by electrolytic action this value can be somewhat increased.

**80. Commercial grades of aluminum.** The impurities most commonly found in aluminum are silicon and iron. Silicon in aluminum exists in two forms, one seemingly combined with aluminum as combined carbon exists in pig iron, and the other as an allotropic graphitoidal modification. Small quantities of copper, sodium, carbon and occluded gases are also found in aluminum. The Aluminum Company of America classifies aluminum commercially in three grades,* as follows:

Extra-pure aluminum, No. 1 grade or so-called pure aluminum, and No. 2 grade for castings, or structural shapes. The average composition is as follows:

| | No. 1 (per cent.) | No. 2 (per cent.) |
|---|---|---|
| Aluminum | 99.55 | 96 |
| Silicon | 0.30 | 2 |
| Iron | 0.15 | 2 |

Pure aluminum (No.1 grade or better) is necessary to secure high electrical conductivity, extreme malleability, ductility and maximum resistance to corrosion. For other purposes small amounts of copper, nickel, tungsten, manganese, chromium, titanium, zinc or tin may be advantageously added to aluminum to produce hardness, rigidity and strength. These metals when alloyed with aluminum do not diminish its resistance to corrosion so much as silicon or iron.

**81. Typical analysis.** The following analyses of aluminum are typical.

| | Aluminum Co. of Amer.† (per cent.) | Richards (per cent.) |
|---|---|---|
| Aluminum | 99.57 | 99.25 |
| Silicon | 0.29 | 0.64 |
| Iron | 0.14 | 0.04 |
| Copper | ..... | 0.02 |
| Lead | ..... | 0.01 |

**82. Methods of working aluminum** are described at some length in a publication issued by the Aluminum Company of America.* Sections or shapes similar to those in which steel is rolled can be made of aluminum and its alloys; sheets can be rolled commercially as thin as No. 40 A.W.G. Aluminum can also be stamped, drawn, beaten, spun, forged, extruded and machined, with suitable methods, tools, dies and lubricants. Aluminum can be drawn into a great variety of forms; except for slight differences, the methods used in drawing copper wire are applicable. Like most other metals it is hardened and strengthened by working, and softened again by annealing. The annealing temperatures depend on the composition of the metal, but probably lie between the limits of 343 deg. cent. (650 deg. fahr.) and 482 deg. cent. (900 deg. cent.).

Cleaning or pickling is done by dipping first in benzene and then in hot caustic alkali (such as caustic soda or caustic potash), in nearly saturated solution. Upon removal the metal should be washed in cold running water and next immersed in a hot solution of strong nitric acid, to neutralise the caustic. Finally it should be washed in hot running water and then quickly dried in hot air; small articles should be placed in sawdust.

The ordinary low-temperature solders, containing lead, are not suitable for soldering aluminum, since the surface oxide will not dissolve under the action of a flux or salt as in the case of copper, tin, or zinc. The temperature at which solder alloys with aluminum is approximately 349 deg. cent. (660 deg. fahr.). It is first necessary to tin the surface of aluminum by heating it in a hot flame (blow-torch) and pour over it melted tin or half-and-half solder, but Richards solder is the best; meanwhile the solder should be rubbed into the surface with a fine metal brush. In this way the oxide is melted and the solder is alloyed with the aluminum. After this tinning operation is completed, the usual soldered joint may be made. Joints in bare line conductors are usually made with sleeves or with clamps (see Sec. 11). Clamps are also used for joining aluminum conductors to copper or steel conductors; sweated bushings† are employed, of suitable metal to prevent electrolytic corrosion in the joint.

Aluminum rod can be readily butt-welded by merely pressing the ends together in the flame of a blowlamp. No flux is necessary for this process. It is also possible to weld aluminum by the autogenous process and this method is generally adopted for jointing plate or sheet.

It is easy to obtain quite as good a machined surface with aluminum as any other metal. Lubricants should be used only for drilling and screwing and then only paraffin. Filing should be done with a single cut file as cross-cut files are readily clogged. Aluminum will take and retain a very high polish, fully equal to that of silver.

**83. Density.** The value for the density of commercial hard-drawn aluminum, accepted by the Bureau of Standards,‡ is 2.70. The Aluminum Company of America gives 2.56 for pure cast aluminum, 2.66 for annealed wire and sheets, and 2.68 for unannealed wire and sheets. The British Aluminum Company, Ltd., gives 2.56 to 2.60 for castings, and 2.71 for rolled or drawn aluminum. The Smithsonian Physical Tables (5th rev. ed., p. 85) give 2.56 to 2.58 for castings and 2.65 to 2.80 for wrought aluminum. The Encyclopædia Britannica (ed. of 1910, Vol. I, p. 771) gives 2.583 for castings and 2.688 for rolled aluminum at 4 deg. cent. Mr. H. W. Buck§ gives 2.68 for aluminum wire.

The best average value from the foregoing authorities seems to be 2.57 for castings and 2.69 for sheets or wire. The latter value is in close agreement, for engineering purposes, with the value 2.70 used by the Bureau of Standards and taken as the basis of the aluminum wire tables in this section (Par. 91). A density of 2.70 g. per cu. cm. corresponds to 0.09755 lb. per cu. in.

**84. Resistivity.** Much less has been published about the effect of impurities on the conductivity of aluminum than in the case of copper, and such

Digitized by Google

information at the present time is largely regarded as among the secrets of the trade. The ordinary percentage of impurities in commercially pure aluminum, No. 1 grade (see Par. 80), is 0.45 per cent. In terms of the British standard for hard-drawn copper at 60 deg. fahr. (15.6 deg. cent.) Mr. Burkewood Welbourn stated* that a (volume) conductivity of 60 per cent. corresponds to 0.71 per cent. of impurities, and a conductivity of 61.7 per cent. corresponds to 0.5 per cent. of impurities.

The Aluminum Company of America states† that the electrical (volume) conductivity of pure (No. 1 grade) aluminum is about 62 per cent. in the Matthiessen standard scale. The British Aluminum Company, Ltd., gives (June, 1914) the following values of resistivity, expressed in microhm-cm.

| | Annealed | Hard-drawn |
|---|---|---|
| Volume resistivity, microhm-cm. at 60 deg. fahr... | 2.770 | 2.870 |
| Volume resistivity, microhm-cm. at 32 deg. fahr... | 2.610 | 2.70 |

The Bureau of Standards‡ gives the following average values of resistivity for commercial hard-drawn aluminum.

| | |
|---|---|
| Mass resistivity, ohms (meter, gram), at 20 deg. cent. | 0.0764 |
| Mass resistivity, ohms (mile, pound), at 20 deg. cent. | 436.0 |
| Mass per cent. conductivity | 200.7 |
| Volume resistivity, microhm–cm., at 20 deg. cent. | 2.828 |
| Volume resistivity, microhm–in., at 20 deg. cent. | 1.113 |
| Volume per cent. conductivity | 61.0 |
| Density, g. per cu. cm. | 2.70 |
| Density, lb. per cu. in. | 0.0975 |

These values given by the Bureau of Standards are the basis of the aluminum wire tables in Par. 87. Since aluminum is very rarely used as an electrical conductor in the soft state, the foregoing values given by the Bureau of Standards, for hard-drawn wire, have the most commercial significance. Annealed aluminum, however, is used abroad for the conductors of underground cables.

**85. Temperature coefficient of resistance.** On the authority of the British Aluminum Company, Ltd., the temperature coefficient of resistance of aluminum, for constant mass, varies from 0.0032 to 0.0040 per deg. cent. and from 0.0018 to 0.0022 per deg. fahr.

A determination made in the laboratory of the Westinghouse Electric and Manufacturing Company, under the direction of Prof. Charles F. Scott, gave as the average coefficient between 0 deg. and 50 deg. cent., the value 0.00388 per deg. cent.; in the fahrenheit scale the equivalent of this value is 0.00216 per deg. Prof Scott's determination is quoted by the Aluminum Company of America.

The Bureau of Standards gives 0.0039 per deg. cent. at 20 deg. cent. (circular No. 31, Third Edition, 1914, p. 14.)

**86. Aluminum wire tables.** The complete tables for aluminum wire given in Par. 87 were taken from circular No. 31, Third Edition, issued by the Bureau of Standards, and are based on a volume conductivity, in terms of the annealed copper standard, equal to 61.0 per cent.

Aluminum wire is practically never used in single strands for overhead construction, but the tables are very useful in computing the resistance of concentric strand. In commercial practice the aluminum delivered under contract varies in conductivity from 60 per cent. to 62 per cent. of the former Matthiessen standard, many contracts being placed at 61 per cent.

**88. Aluminum cable tables** are given in the following paragraph. The values of resistance and weight per 1,000 ft. are 2 per cent. greater than for a solid rod equal to the combined cross-sections of the wires of the cable; this increment corresponds to a pitch of 15.7. The component wires are assumed to have the same value of resistivity as the hard-drawn aluminum in Par. **87**, temperature differences being allowed for. See Par. **55** to **59** on the general properties of concentric strands.

**90. Reinforced (steel centre) aluminum concentric strand.** A concentric strand consisting of six hard-drawn aluminum wires laid over a centre or core consisting of a galvanized steel wire has been manufactured to a very limited extent, for experimental use. The steel employed had a tensile strength of about 125,000 lb. per sq. in. On account of the different coefficients of expansion, with these metals, the distribution of stresses in a suspended cable under changing temperature conditions is quite complicated.

In another instance the core was composed of 7 strands of steel laid into a concentric cable; about this were laid 6 strands of hard-drawn aluminum. The tensile strength of the steel was about 220,000 lb. per sq. in. and the strength of the aluminum was 28,000 lb. per sq. in. This type of conductor was used in a 1,000-ft. ravine span. See *Electrical News*, Vol. XXII, p. 34; also *The Canadian Engineer*, Dec. 11, 1913, "Transmission Line Work;" by E. V. Pannell.

**91. Coefficient of linear expansion.** The value given by Sir Roberts-Austen for the linear coefficient of expansion is 0.0000231 per deg. cent. from 0 to 100 deg. cent.; the corresponding value per deg. fahr. is 0.0000128. The value per deg. cent. given by the British Aluminum Company is 0.0000234. The 5th revised edition (1910) of the "Smithsonian Physical Tables" (Fowle, F. E.) gives the coefficient as 0.00002313 at 40 deg. cent.; the mean value between 0 and 100 deg. cent. is 0.0000222 per deg. cent.

**92. Tensile strength.** The tensile strength of aluminum depends upon its state, previous working and heat treatment. The strength of aluminum is increased by cold working, as in the case of copper. The approximate range of tensile strength of aluminum in various forms is given next below, in lb. per sq. in. (Aluminum Co. of America).

Digitized by Google

| | |
|---|---|
| Castings | 12,000 to 14,000 |
| Sheets | 24,000 to 40,000 |
| Bars | 28,000 to 40,000 |
| Wire | 25,000 to 55,000 |

The tensile strength of aluminum wire, in the sizes used commercially, ranges from 14,000 to 33,000 lb. per sq. in., depending upon the size of the wire and upon its mechanical and heat treatments. **Hard-drawn** aluminum wire, in the sizes usually employed in the construction of concentric cables, ranges from about 23,000 to 27,000 lb. per sq. in. It is possible to produce hard-drawn wire of greater strength than this, but it is likely to be "short" or brittle and is not satisfactory commercially.

The British Aluminum Company, Ltd., gives the following table showing the strength of progressive sizes of hard-drawn wire, which is practically the same as the range stated by the Aluminum Company of America.

| S.W.G. No. | Diam. (in.) | Tensile strength (lb. per sq. in.) | S.W.G. No. | Diam. (in.) | Tensile strength (lb. per sq. in.) |

| 8 | 0.160 | 25,000 | ..... | ..... | ..... |

Soft or annealed aluminum is never used in overhead spans, but is used to some extent for underground cables.

Concentric cables have a breaking strength somewhat less the sum of the breaking strengths of the strands, not usually exceeding 85 to 90 per cent. of the latter. Theoretically the strength of concentric-lay cable is a function of the pitch.

**93. Elastic limit.** Under the definition of Hooke's law, aluminum has no definite elastic limit, because it stretches under load, if the load is held constant for any appreciable length of time. See stress-strain diagrams in Figs. 9 and 10. Taking as the definition of elastic limit, the maximum load under which the material will not continue to stretch, it can be stated that the elastic limit of hard-drawn wire will range from about 12,000 to 17,000 lb. per sq. in., or from 50 to 60 per cent. of the ultimate tensile strength.

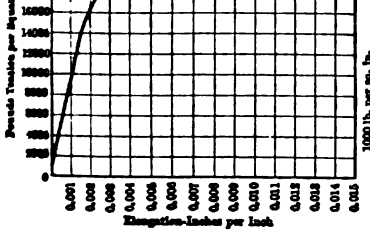

FIG. 9.—Stress-strain diagram of hard-drawn aluminum wire.

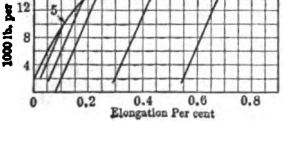

FIG. 10.—Stress-strain diagram of hard-drawn aluminum wire.

**94. Stress-strain diagrams** of hard-drawn wire are given in Figs. 9 and 10. The wire represented in Fig. 9 was 0.162 in. in diameter, cold-drawn from a 0.375-in. annealed rod. Fig. 10 shows a wire of 0.2037 in. diameter, the test length being 60 in. The figures associated with the arrows

Digitized by Google

indicate the number of minutes the load was held at each of several points. This specimen broke at 23,900 lb. per sq. in., with an elongation of 1.25 per cent.

**95. Elongation at rupture.** The total elongation at rupture, for hard-drawn wire in commercial sizes, ranges from about 2 to 4 per cent.

**96. Young's modulus of elasticity** in tension ranges from 8,000,000 to 12,000,000, with an average of 9,000,000 to 10,000,000. F. O. Blackwell gives the modulus for concentric cables as 7,500,000 (Trans. Int. Elec. Cong., St. Louis, 1904, Vol. II, pp. 331–347).

**97. Specific heat** of aluminum at 0 deg. cent. is 0.2089 and at 100 deg. cent. is 0.2226; the mean specific heat between 16 and 100 deg. cent. is 0.2122 (5th rev. ed., "Smithsonian Phys. Tables," p. 228).

**98. Thermal conductivity** of aluminum at 0 deg. cent. is 0.344 gram-calorie (cm-cube) per deg. cent. per sec., with a temperature coefficient of 0.00054 per deg. cent. ("Smithsonian Phys. Tables," 1910).

**99. Aluminum bars** are used in power-plant switchboard connections for bus bars, and for carrying very large currents in electrolytic work. Since bus bars are generally designed to have a stated carrying capacity limited by a stated temperature rise, the comparative cross-sections of aluminum and copper are not required in practice to be in inverse ratio to the respective conductivities, because of the difference in radiating surface.

## COPPER-CLAD STEEL

**100. Compound or bi-metallic wires** composed of copper-covered iron or steel have been manufactured by a number of different methods, and were first attempted many years ago. Aluminum-covered steel has also been tried, on an experimental scale. The general object sought in the manufacture of such wires is the combination of the high conductivity of copper or aluminum with the high strength and toughness of iron or steel. The resulting conductor is obviously a compromise between copper (or aluminum) and iron, being inferior as a whole to the former and superior to the latter.

**101. Union between the metals.** In the early attempts to produce bi-metallic wires, the two metals were not welded, but merely in close physical contact. Consequently there was a marked tendency toward electrolysis wherever moisture and air had access to the junction between the dissimilar metals. No great success attended the use of such wires until modern processes were developed for effecting a weld or molecular union between the metals.

**102. Copper-clad steel wire** is manufactured by two processes, known as the **Monnot process** (Duplex Metals Co.) and the **Griffith process** (Colonial Steel Co.). The Monnot process consists briefly of dipping a mild steel billet in bath of molten copper maintained at high temperature, thus forming on the surface of the billet an iron-copper alloy; the billet is then withdrawn and placed in a mold, and a copper jacket is cast around it. The billet is then re-heated and hot-rolled to wire rods, and finally cold-drawn to wire.

The Griffith process consists briefly of coating a mild steel billet with copper by electrolytic deposition (Sec. 19), then inserting the copper-coated billet in a copper tube, closing the ends, and heating the compound billet preparatory to rolling; it is then hot-rolled to rods, and cold-drawn to wire.

**103. Commercial grades of copper-clad steel wire.** It has become customary commercial practice to rate copper-clad steel wire in terms of the ratio of its volume conductivity to copper. Thus one manufacturer makes three grades of wire, having respectively 30 per cent., 40 per cent. and 47 per cent. conductivity ratio to copper; another manufacturer has standardised a 30-per cent. wire. These ratios are usually average ratios, and in practice certain tolerance limits must be recognised, above and below the average; or else the rated conductivity can be specified as the absolute acceptable minimum.

**106. Properties of copper-clad steel wire** depend upon the relative proportions of copper and steel, the constituents of the latter, the mechanical treatment and the heat treatment. The cold-drawing process hardens the steel core to an unpermissible degree and it becomes necessary at intervals to anneal it before proceeding further with the drawing process. The commercial grades are obtainable either dead soft (annealed) or hard drawn, as desired. The properties of the commercial grades of wire are given in Par. **104** and **105**, taken from the manufacturers' tables. In drawing specifications it is customary to fix tolerance limits, or else minimum (or maximum) limits. For technical articles dealing with the properties of copper-clad steel wire, see the following: *Electrical World*, Vol. LII, pp. 701 and 818; *Scientific American*, Vol. XCVIII, p. 347; *Iron Age*, Vol. LXXVII, p. 52; *Journal of Industrial and Engineering Chemistry*, Sept., 1909; *Electrical World*, Dec. 22, 1910, Dec. 29, 1910 and Jan. 12, 1911; *Telephone Engineer*, Oct., 1910 to July, 1911, inclusive. Proceedings A. S. T. M., Vol. X, pp. 280–294; *Telephone Engineer*, Dec., 1911 to Mar., 1912, inclusive.

**107. Temperature coefficient of resistance** of the 40 per cent. grade of copper-clad steel is approximately 0.0045 per deg. cent., from and at zero. The coefficient ranges from about 0.004 to 0.005, depending apparently upon the constituents of the wire and its physical condition.

**108. Permeability of steel core** is about 70, for small magnetising forces at 800 cycles per sec.; at power frequencies it is from 100 to 125. The maximum permeability will be from 600 to 800 at roughly 5,000 gausses. The measured hysteresis loss in the core of No. 1 A.W.G. wire, at 10,000 gausses (max.), was 15,000 ergs per cu. cm. per cycle. The resistivity of the steel will range from 12 to 13 microhm-cm. at 20 deg. cent., approximately. For method of calculating internal inductance see *Electrical World*, 1910, Vol. LVI, p. 1521.

**109. Coefficient of linear expansion** of the 40 per cent. grade of copper-clad steel is 0.0000129 per deg. cent.

**110. The density** or specific gravity of copper-clad steel depends on the relative proportions of copper and steel. The 40 per cent. grade has a density of 8.2.

**111. Tensile strength** of copper-clad steel depends in great measure upon the kind and condition of steel in the core. The strength of the whole wire will range as high as 80,000 to 100,000 lb. per sq. in., hard-drawn. The typical **stress-strain diagram** is similar to the curve for hard-drawn copper in Fig. 5. The breaking loads are given in the tables, Par. **104** and **105**.

**112. Young's modulus** ranges from $19\times10^6$ to $21\times10^6$ lb. per sq. in. for hard-drawn wire and $16\times10^6$ to $20\times10^6$ for concentric cable.

**113. Specifications** for copper-clad steel wire will be found in the "Manual" of the Railway Signal Association. Also see "Handbook of Overhead Line Construction," N. E. L. A.

## IRON AND STEEL

**114. General properties** of iron and steel are covered in detail in another portion of this section, under "Structural Materials." The so-called iron wire is usually steel, containing carbon, manganese and silicon. The effect of these constituents on the resistivity is discussed in Par. **115**. In general, those elements which increase the tensile strength of steel also increase its resistivity; similarly, the mechanical and heat treatments which increase the strength, again increase the resistivity.

**115. Resistivity of iron.** The researches of Barrett, Brown and Hadfield (Scient. Trans. Royal Dublin Soc., VII, Ser. 2, part 4, 1900; Jour. Inst. Elec. Eng., 31, p. 674, 1902) on the electrical and magnetic properties of iron and iron alloys are especially important. They found that Swedish charcoal iron containing 99.85 per cent. iron had a resistivity of 10.2 microhm-cm.

These investigators also found that 1 per cent. of any element added to pure iron increased its specific resistance by an amount approximately proportional to the specific heat or inversely proportional to the atomic weight of the alloying element.

Yensen gives the following values for different grades of annealed iron (see Bulletin No. 72, Eng. Exp. Sta., Univ. of Ill.), in microhm-cm. at 20 deg. cent.

Digitized by Google

| | |
|---|---|
| Electrolytic iron melted in *vacuo* | 9.9 |
| Swedish charcoal iron remelted in *vacuo* | 10.8 |
| Commercial grades: | |
| Swedish charcoal iron cut from plate | 10.5 |
| Standard transformer steel | 11.0 |
| Silicon (4 per cent.) steel | 51.1 |

Hopkinson tested and analyzed 35 different samples of iron (Phil. Trans. p. 463, Part II, 1885) and found resistivities (microhm-cm.) ranging from 13.78 for wrought iron to 100 for cast iron.

Also see Boudouard, O. "Electric Resistivity of Special Steels," IX, 6, No. 10, Sixth Congress Int. Assoc. for Testing Materials, New York City, 1912.

**116. Preece's tests on resistivity of annealed iron wire** (Munroe and Jameson)

| | Composition | | | | | | Ohms (mile, lb.) at 60 deg. fahr. |
|---|---|---|---|---|---|---|---|
| | Fe | C | Mn | Si | S | P | |
| Swedish charcoal iron | 99.70 | 0.10 | 0.03 | Trace | 0.022 | 0.045 | 4502 |
| Swedish charcoal iron | 99.44 | 0.15 | 0.234 | 0.018 | 0.019 | 0.058 | 4820 |
| Siemens-Martin steel | 99.60 | 0.10 | 0.324 | Trace | 0.035 | 0.034 | 5308 |
| Best puddled iron | 99.11 | 0.10 | 0.234 | 0.09 | 0.03 | 0.218 | 5974 |
| Bessemer steel, soft | 98.74 | 0.15 | 0.72 | 0.018 | 0.092 | 0.077 | 6163 |
| Bessemer steel, hard | 98.20 | 0.44 | 1.296 | 0.028 | 0.126 | 0.103 | 7468 |
| Best cast steel | 97.41 | 0.62 | 1.584 | 0.06 | 0.074 | 0.051 | 8033 |

**117. Effects of different alloying elements upon the resistivity of pure iron** were found by Barrett to be as follows: the values given in the table represent the increase in resistivity (microhm-cm.) resulting from the addition of 1 per cent. of different alloying elements.

| | | | |
|---|---|---|---|
| Tungsten | 2.0 | Carbon | 5.0 |
| Cobalt | 3.0 | Manganese | 8.0 |
| Nickel | 3.5 | Silicon | 13.0 |
| Chromium | 5.0 | Aluminum | 14.0 |

**118. Temperature coefficient of resistance.** The average coefficient per deg. cent., between 0 and 100 deg. cent., based on the measurements by Dewar and Fleming, is 0.00622. This value compares with 0.00635 based on recent measurements published by the Bureau of Standards (Scientific Paper No. 236). The mean value between 0 and 20 deg. cent., determined by Dewar and Fleming, is 0.00527 per deg. cent.

**119. Ingot-iron,** described more fully in Par. **379,** has been found on test to have a volume conductivity of 16.76 per cent. and a mass conductivity of 18.96 per cent., in terms of the International annealed copper standard. See *Elec. Railway Journal*, June 6, 1914, "Pure Ingot Iron for Third Rails." Carbon steel rails containing 0.73 per cent. carbon and 0.34 per cent. manganese, have a volume conductivity equal to 13 per cent. of that of copper. (Also see Sec. 16.) Ingot iron wire weighs about 4,600 lb. per mile-ohm at 20 deg. cent. and has a tensile strength of about 52,000 lb. per sq. in.

**120. Resistivity and temperature coefficient of carbon steel.** Barus and Strouhal found that the temper of carbon steel affected its electrical properties as shown below.

| Temper | Resistivity, microhm-cm. at 0 deg. cent. | Temperature coefficient, per deg. cent. |
|---|---|---|
| Soft | 15.9 | 0.00423 |
| Light blue | 18.4 | 0.00360 |
| Blue | 20.5 | 0.00330 |
| Yellow | 26.3 | 0.00280 |
| Light yellow | 28.9 | 0.00244 |
| Glass hard | 45.7 | 0.00161 |

See "Smithsonian Physical Tables," 5th rev. ed., 1910, p. 263.

**121. Resistivity of cast iron and cast steel.** The resistivity of cast iron is about ten times that of pure iron, owing to both the combined carbon and the graphite; a value of 74.4 microhm-cm. for soft grades and 97.8 microhm-cm. for hard grades is given in the "Smithsonian Physical Tables," 8th rev. ed., 1910, p. 263. This authority also gives 19.1 microhm-cm. for cast steel. The chemical composition, mechanical treatment and heat treatment affect the resistivity in a pronounced manner.

**122. Ohms per mile-pound of galvanized iron wire**
(Telephone and telegraph)

| | Extra Best Best (E. B. B.) | Best Best (B. B.) | Steel |
|---|---|---|---|
| Roebling | 4,700 to 5,000 | 5,600 to 6,000 | 6,500 to 7,000 |
| Amer. Steel & Wire Co. | 4,700 to 5,000 | 5,600 to 6,000 | 6,500 to 7,000 |
| Amer. Elec. Works | 4,700 | 5,500 | 6,500 |

Roebling gives the ultimate strength as equal to the product of the weight in lb. per mile by the following factors: 3.0 for E. B. B.; 3.3 for B. B.; 3.7 for Steel. The ratios used by the Amer. Steel and Wire Co. are respectively 2.5, 2.8 and 3.0.

**123. Table of galvanized iron wire**
(American Steel and Wire Co.)

**125. Permeability of iron wire.** The permeability of iron or soft st wire, in the ordinary commercial sizes, at frequencies of 60 cycles or les from 100 to 125; at 800 cycles, it is about 70. This applies to small magi ising forces, such as exist within the wire due to the current flowing thro it. These values hold for the steel core of copper-clad steel.

**126. Steel rails.** The resistivity of common rail steel varies in considera degree, depending upon the chemical composition. Special soft steels w for third rails have resistivities ranging from 7.9 to 9 times that of copp track rails, from 11 to 13 times that of copper. In manganese steels ratio sometimes exceeds 30. The effective resistance of rails conveying al nating currents will be increased somewhat on account of skin effect a eddy-currents. See "Report of the Electric Railway Test Commissio McGraw-Hill Book Co., Inc., New York, 1906. Also see Par. 119.

**127. Density** of pure iron is 7.86, which is fairly precise for wrought iro and steel. The National Tube Co. computes the weight of steel at 0.2833 lb per cu. in. (489.5 lb. per cu. ft.) and iron at 2 per cent less.

**128. Tensile properties of iron and steel wires.** The tensile prope ties are dependent upon the composition of the metal from which the wire drawn, upon the amount of working the wire has received in the process manufacture and upon the heat treatment. For information upon the effe of the constituents of iron and steel on th tensile properties, see "Structural Mat rials," in another portion of this section.

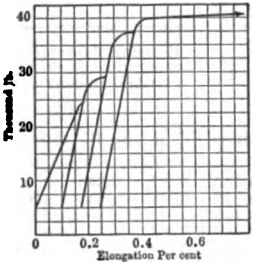

FIG. 11.—Stress-strain diagram of galvanized iron wire.

The tensile strength ranges from abou 45,000 lb. per sq. in., for the purest annealed wrought iron, up to extremely high value for hard steel, in the neighborhood o 500,000 lb. per sq. in. Carbon, manganes and silicon are the chief constituents whic impart strength and hardness; they also in crease the electrical resistivity. Both carbo and manganese decrease the magneti permeability.

The elastic limit and the yield poin occur at about the same relative values a in structural iron and steel; in other words the elastic ratio does not change.

Fig. 11 shows a typical stress-strain dia gram; the wire was 0.164 in. in diameter and broke at 55,100 lb. per sq. in., while th elastic limit was 25,000 lb. per sq. in. an the elongation was 11 per cent. in 60 in. Time was allowed for the wir to set (see Blackwell, F. O. "Conductors for Long Spans;" Trans. Int. Elec Cong., St. Louis, 1904, Vol. II, pp. 331–347).

Blackwell gives Young's modulus as $24 \times 10^6$ lb. per sq. in. for iron wire $27 \times 10^6$ for steel wire, and $22 \times 10^6$ for iron and steel concentric cable.

**129. Coefficient of expansion.** Blackwell gives 0.0000064 per deg. fahr for iron and steel wire.

**130. Specific heat** of wrought iron, from 15 to 100 deg. cent., is 0.115 hard-drawn iron, from 0 to 18 deg., 0.0986 and from 20 to 100 deg., 0.11 ("Smithsonian Phys. Tables," 1910).

**131. Thermal conductivity** of iron in gram-calories (cm-cube) pe deg. cent. is from 0.167 to 0.207 at 0 deg. cent., with a negative temperatur coefficient of 0.00023 "(Smithsonian Phys. Tables," 1910).

## BRONZE

**132. Bronze** is an alloy of copper and tin, with the addition in some case of zinc and other metals. There are numerous varieties of bronze, som designated by a prefix indicating the special or distinguishing constituent, an others known by trade names.

**133. Phosphor bronze** is an alloy of copper, tin and phosphorus, contain ing from 2 to 6 per cent. of tin and 0.05 to 0.13 per cent. of phosphorus. It volume conductivity is not over 35 per cent. of that of copper. Industria bronzes carry zinc and lead, and a larger proportion of phosphorus.

**134. Silicon bronze** is an alloy of copper. silicon and sodium; tin and zin

Digitized by Google

tre also added, in some cases. J. Bucknall Smith ("Wire, Its Manufacture and Uses," London, 1891) gave the following values of conductivity and tensile strength.

| Conductivity (per cent.) | Tensile strength (lb. per sq. in.) | Conductivity (per cent.) | Tensile strength (lb. per sq. in.) |
|---|---|---|---|
| 95 | 56,000 | 45 | 100,000 |
| 80 | 70,000 | 34 | 100,000 |

The grade of silicon bronze used for trolley and span wires has from 2.2 to 2.5 times the resistivity of copper and is from 35 to 70 per cent. stronger.

**136. Properties of bronze wires**
(Perrine)

| Wire | Per cent. conductivity ratio to annealed copper | Tensile strength, lb. per sq. in. | Per cent. elongation |
|---|---|---|---|
| Weiller A bronze | 97.0 | 64,000 | 1 |
| Magnesium-copper | 95.2 | 73,000 | 1 |
| Weiller B bronze | 85.0 | 71,000 | 1 |
| Magnesium-copper | 81.6 | 87,000 | 1 |
| Weiller C bronze | 80.0 | 79,700 | 1 |
| Magnesium-copper | 50.2 | 109,000 | 1 |
| American silicon bronze | 38.8 | 79,000 | 2 |
| Tempered copper | 35.0 | 80,000 | 1 |
| Weiller bronze, French telegraph | 30.0 | 105,000 | 1 |
| Phosphorus bronze | 26.0 | 102,000 | |
| American silicon bronze | 15.8 | 100,000 | 1 |

Also see Parshall and Hobart, "Electric Machine Design," London, 1906; pp. 566 to 567.

**127. Phono-electric wire** is a copper alloy of greater tensile strength and smaller conductivity than hard-drawn copper. The manufacturers claim that it is non-corrosive and perfectly homogeneous in structure, the tensile strength being uniformly distributed over the cross-section normal to the axis of the wire. Tests on No. 0 and No. 00 A.W.G. hard-drawn copper and phono-electric to determine the fusing currents showed that the latter material fused at about 75 per cent. of the current required to fuse the former.

Digitized by Google

Phono-electric wire, on account of its high tensile properties, has been used for trolley wire and for long spans in transmission lines and in telephone and telegraph lines.

The tensile strength of hard-drawn wire ranges from 68,000 to 84,000 lb per sq. in. The total elongation at rupture is about 1 per cent. and Young's modulus is about 18,100,000. The temperature coefficient of resistance is 0.00088 per deg. fahr. and the coefficient of linear expansion is 0.0000144 per deg. fahr.

## MISCELLANEOUS METALS

**138. Resistivity of various metals**
(Compiled from "Smithsonian Phys. Tables," 1910)

| Metal | Resistivity at 0 deg. cent. (microhm-cm.) | Temp. coef. per deg. cent., at 20 deg. cent. | Density | Therm. cond. (g-cal. per cm. cube per deg. per sec.) |

* Average values, for range from 0 to 100 deg. cent.

**139. Tungsten.*** The tungsten metal of commerce, prior to the discovery of ductile tungsten, was a very hard, dark gray powder; in some cases the metal was heated with low-carbon steel in a crucible furnace, producing the alloy known as ferro-tungsten, containing 80 to 85 per cent. of tungsten. The higher-grade alloys are produced in the electric furnace. Cast tungsten is an extremely hard brittle metal, having a specific gravity of about 18.7. In 1910 a process was announced for the production of ductile tungsten, by rolling, swaging or hammering a heated body of coherent tungsten until it becomes ductile at ordinary temperatures (*Electrical World*, Jan. 10, 1914, pp. 77, 78). The melting point is 3,100 ± 60 deg. cent.

**140. Ductile tungsten** is a bright, tough, steel-colored metal, which can be drawn into the finest wire. The operation of wire-drawing increases the strength; Fink stated that tungsten wire of 0.0012 in. diam. had a tensile strength from 580,000 to 610,000 lb. per sq. in., and the density increased from 18.81 before drawing, to 19.30 after drawing to 0.15 in. It retains its luster almost indefinitely. Wrought tungsten has been used as a substitute for platinum contacts in electrical apparatus, for targets or anti-

Digitized by Google

cathodes for Röntgen tubes and for the resistor in electric heater elements; of course its most extensive application is in the form of drawn-wire filaments for incandescent lamps (Sec. 14). The processes of making ductile tungsten are described in British patent No. 2759, issued in 1910; U. S. patent No. 1,082,933 issued Dec. 30, 1913 to W. D. Coolidge. The resistivity at 25 deg. cent. is 5 microhm-cm., annealed, and 6.2 microhm-cm., hard-drawn. The mean temperature coefficient of resistance between 0 and 170 deg. cent. is 0.0051 per deg. cent. The resistance-temperature curve is given in Fig. 12. Coefficient of linear expansion, 20 to 100 deg. cent., $336 \times 10^{-8}$.

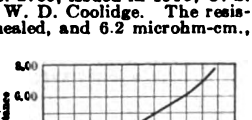

Fig. 12.—Resistance-temperature curve for tungsten.

**141. Tantalum** is a white lustrous metal having a specific gravity of 16.6. It is ductile and workable, and can be drawn into fine wire, in which form it has a tensile strength as high as 130,000 lb. per sq. in. The resistivity at 0 deg. cent. is 14.6 microhm-cm., and the temperature coefficient is 0.0033 per deg. cent.

**142. Wood's fusible alloy** contains 4 parts of bismuth, 2 parts of lead, 1 part of tin and 1 part of cadmium. The melting point is 60.5 deg. cent.

**143. Rose's fusible alloy** contains 2 parts of bismuth, 1 part of lead, and 1 part of tin. The melting point is 93.8 deg. cent.

**144. Composition and melting point of fusible alloys**
(Perrine)

| Composition | | | | | Melting point, deg. cent. |
|---|---|---|---|---|---|
| Tin | Bismuth | Lead | Cadmium | Mercury | |
| ..... | 20 | 20 | ..... | 60 | 20 |
| 4 | 15 | 8 | 3 | ..... | 65 |
| 1 | 2 | 1 | ..... | ..... | 98 |

| 24 | 8 | 22 | ..... | ..... | 164 |
| 67 | 33 | ..... | ..... | ..... | 166 |
| 80 | 20 | ..... | ..... | ..... | 200 |

**145. Fusing currents of different kinds of wires** were investigated by W. H. Preece, who developed the formula

$$I = ad^{\frac{3}{2}} \qquad (12)$$

where $I$ is the fusing current in amperes, $d$ is the diameter of the wire in in. and $a$ is a constant depending upon the material. He found the following values for $a$.

| | | | |
|---|---|---|---|
| Copper | 10,244 | Iron | 3,148 |
| Aluminum | 7,585 | Tin | 1,642 |
| Platinum | 5,172 | Alloy (2Pb–1Sn) | 1,318 |
| German silver | 5,230 | Lead | 1,379 |
| Platinoid | 4,750 | ..... | ..... |

Also see Perrine, F. A. C. "Conductors for Electrical Distribution," New York, 1903; Chap. II.

**146. Selenium** is a non-metallic element chemically resembling sulphur and tellurium and occurs in several allotropic forms varying in specific gravity from 4.3 to 4.8. Selenium melts at 217 deg. and boils at 690 deg.

cent. At zero deg. cent. it has a resistivity of approximately 60,000 ohm–cm. The dielectric constant ranges from 6.1 to 7.4. It has the peculiar property that its resistivity decreases upon exposure to light; the resistivity in darkness may be anywhere from 5 to 200 times the resistivity under exposure to light. See paper by W. J. Hammer, Trans. A. I. E. E., 1903, Vol. XXI, pp. 372 to 393.

## RESISTOR MATERIALS

**148. German silver** is an alloy of copper, nickel and zinc. It is usually listed commercially in terms of its nickel content; thus 18 per cent. wire contains 18 per cent. of nickel. The properties vary considerably with the composition. Perrine gave the following composition of three grades of German silver: 57 Cu, 12.5 Ni, 30.5 Zn; 56 Cu, 20 Ni, 24 Zn; 50 Cu, 30 Ni, 20 Zn. The resistivities were respectively in the ratio 1 : 1.25 : 2.51. Eighteen per cent. alloy has about 18 times the resistivity of copper, and 30 per cent. alloy has about 28 times the resistivity of copper. See Par. **147.**

**149. Copper-manganese alloy** containing either nickel or aluminum is used for resistors, and has a very low temperature coefficient. The alloy composed of copper, ferro-manganese and nickel, or copper, manganese and nickel, is known as **manganin.** The composition of manganin varies somewhat, one formula being 65 Cu, 30 Fe-Mn, 5 Ni.

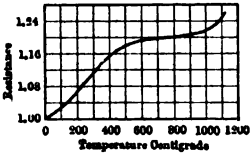

FIG. 13.—Resistance-temperature curve for nichrome.

**150. Copper-nickel alloy** is used extensively for resistor wires. The alloy of copper and nickel found in nature is known as Monel metal (Par. **399**). See Par. **147.**

**151. Nickel-steel alloy** has a very high electrical resistivity but is not as resistant to corrosion, for resistor service, as some other alloys. The nickel-chromium alloys are superior in the respect of having somewhat larger resistivity. See Par. **147.**

**152. Nickel-chromium alloy** is used for resistor wires where very high resistivity is desired. One alloy of this kind has a resistivity of more than 700 ohms per mil-ft. The nickel-chromium alloy known as "Nichrome" has a characteristic resistance-temperature curve of the form shown in Fig. 13.

## CARBON AND GRAPHITE

**153. Forms of carbon.** Carbon occurs in two forms, amorphous and crystalline. The crystalline forms include **diamond** and **graphite,** the latter also being known as **plumbago.** The amorphous forms include charcoal, coke, lamp black, bone black; coal is an impure variety of amorphous carbon. The density of carbon in the diamond state is 3.47 to 3.56; graphite, 2.10 to 2.32; charcoal, 0.28 to 0.57; coke, 1.0 to 1.7; gas carbon, 1.88; lampblack, 1.7 to 1.8.

**154. Resistivity.** The resistivity of amorphous carbon (petroleum coke) at ordinary temperature (25 deg. cent.) may be taken as varying between 3,800 and 4,100 microhm-cm. An average value for retort carbon, such as used for electrodes in electric furnaces, at about 3,000 deg. cent., may be taken as 720 microhm-cm. Graphite at 3,000 deg. cent. has a resistivity of approximately 812 microhm-cm. Experiments by Mr. C. A. Hanson* made in the research laboratory of the General Electric Company show that the resistivity of carbon depends upon the temperature at which it is fired. As the temperature of firing increases, the resistivity decreases, approaching a constant value which is approximately the same as that of graphite. If carbon be heated above the temperature at which it was fired, its resistivity is permanently decreased, and upon cooling it will not return to its original value, but to a value corresponding to that which it would have if fired at the temperature to which it has been heated. Also see table of brush characteristics, Par. **155,** and electrode carbon, Par. **159.**

Experiments made by Morris Owen show that graphite possesses magnetic susceptibility, and under certain conditions the electrical resistivity is increased in very marked degree by magnetization.

**156. Resistance of arc lamp carbons.** The resistance of ½ in. × 12 in. enclosed arc carbons varies from 0.012 to 0.015 ohms per linear inch. Other sizes down to ¼ in. diameter vary according to their cross-sectional areas. The resistance of a ¼-in. diameter projector carbon varies from 0.009 to 0.011 ohms per linear inch. The ½-in. and $\frac{5}{16}$-in. carbons vary according to their cross-sectional areas.

All high-grade forms of carbon, such as that used in the manufacture of search-light carbons and also enclosed arc carbons, may be given the value of about 0.002 ohms per cu. in. Flame-arc carbon material such as is used in the homogeneous electrodes varies from 0.004 to 0.006 ohms per cu. in. All the above values are for ordinary room temperatures.

**157. Temperature coefficient of resistance.** Carbon exhibits a decreasing electrical resistivity and a decreasing thermal resistivity with rising temperature. Graphite exhibits but little change in electrical resistivity, tending downward with rising temperature, but its thermal resistivity increases slightly with rising temperature. The coefficients vary over a considerable range; see Landolt and Bornstein, "Physikalish-Chemische Tabellen," 1912.

**158. Resistances of carbon contacts** vary with pressure, current and time. See results of investigation published by A. L. Clark in the *Physical Review*, Jan., 1913.

**159. Electrode properties of carbon and graphite** were given by Hering in his paper, "The Proportioning of Electrodes for Furnaces" (Trans. A. I. E. E., Vol. XXIX, 1910, pp. 485–545), from experimental determinations. The table below is abstracted from Table I in Hering's paper above mentioned; the paper itself gives elaborate details and many curves. Other papers by Hering on this general subject are noted below.*

| Material | Furnace temp. (deg. cent.) | Temp. drop (deg. cent.) | Electrical resistivity, ohm (in-cube) | Thermal conductivity, †watts (in-cube) |
|---|---|---|---|---|
| Carbon..... | 20.0 | 0.0 | 0.00181 | ..... |
| | 360.0 | 260.0 | 166 | 0.95 |

† 1 watt = 0.2389 g-cal. per sec.; 1 g-cal. per sec. = 4.186 watts.

## SKIN EFFECT

**160. Skin effect** is briefly defined in Sec. 2. Also see Sec. 12, Par. 41.

**161. Formulas and tables for skin effect.** If $R'$ is the effective resistance of a linear cylindrical conductor to sinusoidal alternating current of given frequency and $R$ is the true resistance with continuous current, then

$$R' = KR \qquad \text{(ohms)} \qquad (13)$$

where $K$ is determined from the table in Par. 165, in terms of $x$. The value of $x$ is given by

$$x = 2\pi a\sqrt{\frac{2f\mu}{\rho}} \qquad (14)$$

* "Laws of Electrode Losses in Electric Furnaces;" *Trans.* A. E. S., Vol. XVI, 1909.
"Empirical Laws of Furnace Electrodes;" *Trans.* A. E. S., Vol. XVII, 1910.
"The Design of Furnace Electrodes;" *Electrical World*, June 16, 1910.

Digitized by Google

where $a$ is the radius of the conductor in cm., $f$ is the frequency in cycles per sec., $\mu$ is the magnetic permeability of the conductor (here assumed to be constant) and $\rho$ is the resistivity in absohms ($10^{-9}$ ohm) per cm-cube.

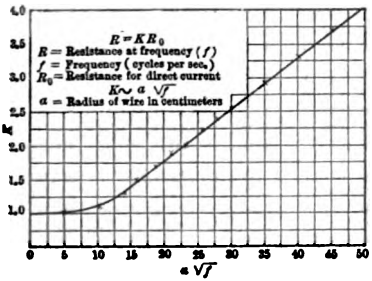
If $L'$ is the effective inductance of a linear conductor to sinusoidal alternating current of a given frequency and $L$ is the true inductance with continuous current, then

$$L' = L_1 + K'L_2 \tag{15}$$

where $L_1$ is the external portion of the inductance, $L_2$ is the internal portion (due to the magnetic field within the conductor) and $K'$ is determined from the table in Par. 165 in terms of $x$. Thus the total effective inductance per unit length of conductor is

$$L = 2\log_e\left(\frac{d}{a}\right) + K'\left(\frac{\mu}{2}\right) \tag{16}$$

See Sec. 2 for further discussion of inductance of linear conductors; also see Sec. 11. For details underlying the above formulas see Bulletin of the Bureau of Standards, Vol. VIII, No. 1, pp. 172 to 181; 1912. Fig. 14 shows values of $K$ in terms of $a\sqrt{f}$ for cylindrical copper conductors of 100 per cent. conductivity.



$R = KR_0$
$R$ = Resistance at frequency ($f$)
$f$ = Frequency (cycles per sec.)
$R_0$ = Resistance for direct current
$K \propto a\sqrt{f}$
$a$ = Radius of wire in centimeters
K
$a\sqrt{f}$

Fig. 14.—Curve showing the proportional change in effective resistance of cylindrical copper conductors with alternating currents.

Fig. 15.—Skin effect in copper-clad steel wires at 60 cycles.

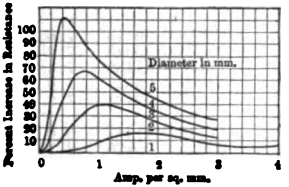


Fig. 16.—Skin effect in iron wires at 50 cycles.

**162. Skin effect in copper-clad steel wire** is illustrated in Fig. 15, based on tests of the effective resistance of solid round wires at 60 cycles per sec. The effects at 25 cycles are somewhat less. The effects in large concentric-lay cables are somewhat greater, and the increase at 60 cycles reaches values as high as from 80 to 100 per cent.; when the core is composed of solid copper, the skin effect is less severe. In the smaller wires (No. 10 to No. 12 A.W.G.) the skin effect at 800 cycles per sec., with currents of telephonic strength, range from 3 to 6 per cent. (increase of resistance).

**163. Skin effect in iron wire** at 50 cycles is illustrated in Fig. 16, based on data supplied by the Felten & Guilleaume Carlswerke (Elek. Zeit., Dec.

Digitized by Google

10, 1914). In No. 12 B.W.G. iron wire (B. B. grade), at 800 cycles per sec., and with currents of telephonic magnitude, the increase in resistance was found by measurement to be 47 per cent. See Par. 203.

**164. Effect of very high frequencies on iron** has been investigated by E F. W. Alexanderson; see "Magnetic Properties of Iron at Frequencies up to 200,000 Cycles," *Trans.* A. I. E. E., Vol. XXX, 1911, pp. 2433–2454. He concluded that the permeability is unaffected by the frequency. In applying Steinmetz's formula for skin effect (see "Transient Electric Phenomena and Oscillations," New York, 1909), he recommended using average constants as follows: permeability, 2,250 and conductivity, $0.9 \times 10^6$, for soft iron.

**165. Table of constants for skin-effect formulas**

# MAGNETIC MATERIALS

## CLASSIFICATION

**168. Paramagnetic materials** include all those materials in which the intensity of magnetization (Sec. 2) is a positive quantity. The principal paramagnetic materials are iron, nickel, cobalt, and certain of their alloys; also certain non-ferrous alloys, known as the Heusler alloys. The only materials of great industrial importance are iron and its alloys.

**169. Diamagnetic materials** are those which are less magnetic than ether or air, or in which the intensity of magnetization is negative. There is no known material in which this effect has more than a very feeble intensity. Bismuth is the leading example of materials of this class.

**170. Commercial magnetic materials** can be classified as follows: cast iron, semi-steel, wrought or puddled iron, soft or low-carbon steel, high-carbon steel, and alloy steel. These are the materials whose properties are important in practical engineering work.

**171. Retentive and non-retentive materials.** The commercial materials are divisible as a whole into two classes, one suitable for all applications in which the retentivity, coercive force and hysteresis should be as small as possible, the other suitable for applications in which maximum retentivity is the most-desired characteristic. The former class is useful in all types of electromagnetic mechanisms, such as generators, motors, transformers, electromagnets, etc.; the second class is useful only in permanent magnets, measuring instruments, magnetos, relays, etc.

## COMPOSITION AND PROPERTIES

**172. Dependence of properties upon composition and treatment.** The magnetic properties of all materials depend upon the chemical composition, heat treatment and mechanical treatment. These factors are considered in some detail in the succeeding paragraphs.

**173. Effect of impurities on magnetic properties of iron.** The general effect of impurities is to decrease the permeability and increase the iron loss. Most impurities are as a whole injurious in their effect, but there are certain apparent exceptions. The effect of silicon appears to be to decrease the iron loss and increase the permeability up to inductions from 12,000 to 14,000

Digitized by Google

gausses, after which the permeability decreases below that of soft iron, while the iron loss begins to increase rapidly. See also Ruder, W. E., "The Effect of Chemical Composition upon the Magnetic Properties of Steels;" *General Electric Review*, March, 1915, pp. 197 to 203.

**174. Effect of carbon.** Carbon increases the resistivity, decreases the permeability, lowers the saturation point and increases the coercive force and the retentivity. Concurrently the hysteresis loop is broadened and its area increased. These effects are greater in hardened steel than in soft or annealed material. In slowly cooled iron-carbon alloys the carbon exists as pearlite up to the eutectoid point (about 0.85 carbon); above this point the carbon exists as cementite ($Fe_3C$). The cementite carbon diminishes the conductivity less than does the pearlite carbon. At a quenching temperature of 850 deg. cent. the limit of dissolved carbon is about 1.4 per cent.; no excess of carbon above 1.4 is soluble at this temperature.

**175. Effect of manganese.** Very small proportions of manganese are not injurious in any substantial degree, but it is customary to limit the proportion of manganese as much as practicable. The true effect of small proportions of manganese is difficult to determine because of its association in most cases with carbon. See *Jour.* I. E. E., April, 1911, Vol. XLVI, No. 206, pp. 263 to 266. When the manganese content reaches 12 per cent. the steel becomes practically non-magnetic.

**176. Effects of silicon and aluminum.** The researches of Barrett, Brown and Hadfield (1900 and 1902) established the fact that the only magnetic alloys superior to the purest commercial iron are the alloys of iron with silicon, and with aluminum. The best silicon alloy contained 2.5 per cent. of silicon, and the best aluminum alloy contained 2.25 per cent. of aluminum.

| | Maximum permeability | $\mathfrak{G}$ for maximum permeability | Hysteresis loss, ergs per cu. cm. per cycle for $\mathfrak{G}$ (max) = 9,000 | Coercive force for $\mathfrak{G}$ (max) = 17.700 |
|---|---|---|---|---|
| Swedish charcoal iron..... | 2,100 | 4,000 | 2,334 | 1.10 |
| 2.5 per cent. silicon..... | 5,000 | 4,000 | 1,549 | 0.80 |
| 2.25 per cent. aluminum.. | 5,400 | 5,000 | 1,443 | 0.80 |

Guggenheim has shown (Elek. Kraft U. Bahnen, Sept. 24, 1910), for iron containing 0.2 per cent. of carbon, that silicon in quantities up to 1.8 per cent. decreases the permeability, but from 1.8 to 5 per cent. it improves the permeability and decreases the hysteresis loss; for $\mathfrak{G}$(max) = 10,000 in sheets 0.5 mm. thick the hysteresis loss was 2,910 ergs per cu. cm. per cycle, for best silicon steel, compared with 6,000 ergs for ordinary sheet iron.

For electrical and mechanical effects of silicon and aluminum, see appropriate portions of this section.

**177. Effect of nickel.** The addition of nickel, up to 2 per cent., causes little change in magnetic quality (Burgess and Aston). A higher nickel content rapidly decreases the permeability. At 25 to 30 per cent. nickel, the magnetic properties are greatly impaired, but improve again upon a further increase in nickel.

**178. Effects of tungsten, chromium and molybdenum.** These elements have the general property of increasing the magnetic hardness and particularly the coercive force, making a very desirable steel for permanent magnets. See "Magnet Steel," Par. **225** to **230**.

**179. Effects of arsenic and tin.** These elements are similar in their effects to silicon and aluminum, increasing the resistivity and reducing the hysteresis loss. Tin increases the permeability at higher inductions and decreases the hysteresis loss even more than silicon.

**180. Sulphur, phosphorus and oxygen** are in general injurious in their effects, even in small percentages.

Digitized by Google

**181. Effect of heat treatment.** Suitable heat treatment during manufacture reduces the iron loss, increases the permeability and gives better physical properties. The best physical properties and the permeability are to some extent opposed, and the most suitable heat treatment as regards magnetic properties is not generally the one which gives the highest physical properties. The general method of annealing is in boxes, under cover, with slow cooling.

**182. Effect of temperature.** Both iron and steel lose their magnetic properties at about 750 to 800 deg. cent., and are non-magnetic above that temperature. The exact temperature at which this transformation occurs is somewhat variable, and depends upon the chemical composition of the metal.

**183. Effect of temperature on permeability.** Hopkinson's experiments (Phil. Mag. and Proc. Roy. Soc.) showed that with weak magnetising forces the permeability increases with rises of temperature up to the critical point, or about 785 deg. cent., above which iron becomes non-magnetic. Under moderate magnetising forces the permeability first increases slightly, with rise of temperature, and then decreases rapidly as the critical point is approached. Under strong magnetising forces the permeability suffers no change at first, and then decreases gradually as the critical point is approached. See Chap. VIII of Ewing's "Magnetic Induction in Iron and Other Metals."

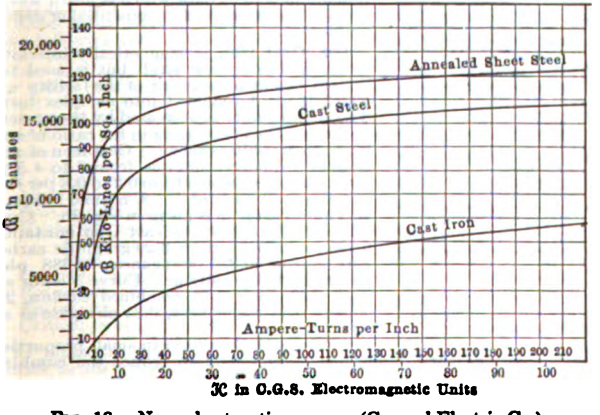

FIG. 18.—Normal saturation curves (General Electric Co.).

**184. Normal saturation curves** for cast-iron, cast-steel and annealed-steel (low-carbon) sheets, of the qualities ordinarily used in electrical construction, are given in Fig. 18. Also see Fig. 37 (Par. **79**) in Sec. 8; Fig. 33 (Par. **85**) in Sec. 7; and "Commercial Sheets" in this section. For precautions and rules in extrapolating magnetization curves see Ball, J. D., *General Electric Review*, Jan. 1915, pages 31 to 33.

**185. Induction-permeability curves** for cast iron and malleable iron are given in Fig. 19. These curves are typical of the shape of induction-permeability curves in general.

**186. Aging.** Aside from the immediate change in the magnetic quality of iron which results from heating, it produces a slow deterioration which results in reduced permeability and increased hysteresis. Even so low a temperature as 50 deg. cent., if continued for some weeks, will produce an appreciable effect. The tests by S. R. Roget (*Proc.* Roy. Soc., May 12, 1898 and Dec. 8, 1898) showed that the hysteresis loss increased 9 per cent. when the iron was

Digitized by Google

heated for 27 days at 50 deg. cent.; 53 per cent. when heated for 25 days at 65 deg. cent.; 89 per cent. when heated for 25 days at 87 deg. cent.; 140 per cent. when heated for 25 days at 135 deg. cent. Also see Mordey, W. M., *Proc.* Roy. Soc., June, 1895; also see aging tests in "Electric Machine Design," by Parshall and Hobart; Allen, T. S., "The Comparative Aging of Electric Sheet Steels;" *Electrical World*, 1908, Vol. LII, p. 579.

**187. Non-aging steel.** Silicon-steel, aside from having low hysteresis and high resistivity, also possesses the valuable property of being non-aging. That is to say, its magnetic properties are not impaired by prolonged heating at moderate temperatures, but on the contrary may be slightly improved. While as much as 3 to 4 per cent. of silicon is present in silicon-steel, it is also useful, in much smaller quantities, in improving the aging qualities of low-carbon steel. Parshall and Hobart recommend ("Electric Machine Design," p. 36) the following composition for sheet steel having good aging qualities: carbon, 0.06; manganese, 0.50; silicon, 0.01; sulphur, 0.03; phosphorus, 0.08.

**188. Effects of mechanical stress on magnetization.** Ewing states (Chap. IX, "Magnetic Induction in Iron and Other Metals") that the presence of any moderate amount of longitudinal pull increases the susceptibility when the magnetism is weak, but reduces it when the magnetism is strong. With hardened metal the effects of stress are in general much greater than with annealed metal.

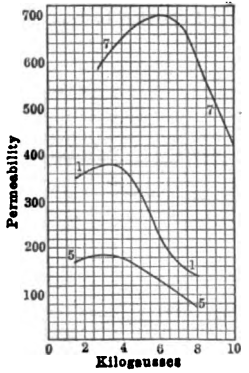

FIG. 19.—Induction-permeability curves of cast iron and malleable iron.

**189. Page effect** is the faint metallic sound resembling a light blow which is heard when a piece of iron is suddenly magnetized or demagnetized.

**190. Cast iron** is magnetically inferior to wrought iron or low steel, but is used to a limited extent on account of the facility with which it can be molded into complex forms. The permeability is decreased by the presence of carbon, the effect being in the ratio of combined to graphitic carbon. Cast iron of good magnetic quality contains from 3 to 4.5 per cent. carbon, of which from 0.2 to 0.8 per cent. is in the combined form. A normal induction curve for cast iron is given in Fig. 18. Curve 1 in Fig. 19 applies to cast iron containing 0.195 combined carbon, 3.29 graphitic carbon, 2.01 silicon, 0.320 manganese, 0.988 phosphorus and 0.08 sulphur. Curve 5 is for cast iron containing 0.72 combined carbon, 2.07 silicon, 0.38 manganese, 0.85 phosphorus and 0.035 sulphur.

Silicon and aluminum in small proportions make the casting more homogeneous and tend to reduce the combined carbon. Silicon tends also to counteract sulphur.

**191. Malleable cast iron** is magnetically superior to cast iron, being lower in combined carbon and improved by the heat treatment which it receives. Curve 7 in Fig. 19 is for malleable cast iron (see Parshall and Hobart, "Electric Machine Design") containing 0.83 combined carbon, 2.201 graphitic carbon, 0.93 silicon, 0.116 manganese, 0.039 phosphorus and 0.080 sulphur.

**192. Wrought iron** is among the best of magnetic materials from the standpoint of permeability, but has higher core losses than silicon steel. See Par. **100** comparing Swedish iron with other materials.

**193. Rolled steel** of the low-carbon variety is used very extensively in the form of electrical sheets and rods. A normal induction curve is shown in Fig. 18. Commercial sheets are described in Par. **217** to **224**.

**194. Cast steel** is extensively used for those portions of magnetic circuits which carry uniform or continuous flux and need superior mechanical strength. Parshall and Hobart state ("Electric Machine Design," p. 22) that cast steel of good magnetic qualities should be limited in its composition as follows: combined carbon, 0.25; silicon, 0.20; manganese, 0.50; phos-

Digitized by Google

phorus, 0.08; sulphur, 0.05. A normal induction curve is shown in Fig. 18.

**195. Alloy steel.** The principal alloy steel in extensive use is silicon steel. Its properties are covered under "Commercial Sheets," Par. **217** to **224**, and Figs. 24 and 26. It is low in core loss, non-aging, and high in permeability except at the higher densities. Tungsten steel and tungsten-chrome steel are used extensively for permanent magnets; see "Magnet Steel," Par. **225** to **230**. **Mitis iron** is steel to which has been added a small proportion of aluminum, ranging from 0.06 to 0.27 per cent. Magnetically it is a little better than ordinary steel up to densities of about 100 kilolines per sq. in., and inferior at higher densities. See Parshall and Hobart, "Electric Machine Design;" published by *Engineering*, London, 1906; p. 26.

**196. Best composition of dynamo sheets; De Nolly and Veyret.** High carbon and cold working are both injurious to electrical sheets. The recommended composition and treatment is as follows: (1) The steel should have less than 0.1 per cent. carbon, from 3 to 4 per cent. silicon, less than 0.3 per cent. manganese, less than 0.03 per cent. sulphur and phosphorus; (2) the sheets after rolling should be annealed at 750 to 800 deg. cent. with slow cooling; (3) the rolling should be finished at low temperature; (4) after final annealing, no cold working should be allowed (IX 5, No. 9, Sixth Congress of Int. Assoc. for Testing Materials, New York City, 1912).

**197. Electrolytic iron melted in vacuo.** "Magnetic and Other Properties of Electrolytic Iron Melted in Vacuo" is the subject of a valuable monograph by T. D. Yensen, and is published as Bulletin No. 72, Engineering Experiment Station, Univ. of Ill., 1914; this monograph is the source of the following data.

The electrolytic iron was doubly refined from Swedish charcoal iron anodes, and contained from 99.97 to 99.98 per cent. of chemically pure iron, 0.006 carbon and 0.01 silicon. The iron as deposited was crushed, cleaned and placed in a magnesia crucible; then it was melted in a vacuum furnace and allowed to cool. Finally it was hot forged to rods about 0.5 in. diameter and 20 in. long. The average results from rods annealed at 900 deg. cent. were as follows:

| | |
|---|---|
| Carbon content, per cent | 0.0125 |
| Maximum permeability | 12,950 |
| Flux density at maximum permeability | 6,550 |
| Hysteresis loss, ergs per cu. cm. per cycle: | |
| At $\mathfrak{G}$ (maximum) = 10,000 | 1,060 |
| At $\mathfrak{G}$ (maximum) = 15,000 | 1,990 |
| Coercive force, $\mathfrak{G}$ (maximum) = 15,000 | 0.34 |
| Retentivity, $\mathfrak{G}$ (maximum) = 15,000 | 9,940 |
| Resistivity (microhm-cm.) at 20 deg. cent. | 9.96 |
| Critical temp., deg. cent. | 894 |

The magnetic quality of electrolytic iron melted *in vacuo* is decidedly superior to any grade of iron thus far produced; the maximum permeability obtained was 19,000 at a density of 9,500 gausses, and the average hysteresis loss obtained is less than one-half that found in the best grades of commercial transformer iron. Swedish charcoal iron melted *in vacuo* approaches electrolytic iron in magnetic quality, due chiefly to reduction of carbon content. Low-carbon iron melted *in vacuo* will lose 50 to 90 per cent. of its original carbon. Electrolytic iron is at present purely a laboratory or experimental product, and therefore too expensive for commercial applications. See the bibliography appended to Mr. Yensen's monograph. Also see *Proc.* A. I. E. E., Feb., 1915, pp. 237–261.

**198. Approximate saturation values** of different magnetic materials are given by Steinmetz as follows, in gausses.

| | | | |
|---|---|---|---|
| Iron | 20,000 | Magnetite | 5,000 |
| Cobalt | 12,000 | Manganese alloys up to | 4,000 |
| Nickel | 6,000 | | |

**199. Maximum saturation intensity.** Hadfield and Hopkinson have shown that a great number of magnetic materials, including commercially pure iron and many iron alloys, have a definite saturation intensity of

Digitized by Google

magnetism (Hadfield, Sir R. A. and Hopkinson, B., "The Magneti Properties of Iron and Its Alloys in Intense Fields," *Jour.* I. E. E., Apri 1910, Vol. XLVI, pp. 235–306). The intensity of magnetization is defined a the quantity $J$ in the formula $\mathfrak{B} = \mathfrak{H} + 4\pi J$, or the magnetic moment pe unit of volume.

Every alloy which they examined was found to have a definite saturatio intensity of magnetism, which they termed the **specific magnetism** This intensity was reached in most cases in a field of 5,000 units. Th specific magnetism of commercially pure iron of density 7.80 was found t be 1,680 within 1 per cent. The presence of carbon in annealed iron-carbo steel reduces the specific magnetism by a percentage equal to six times th percentage of carbon, if other elements are present only in small propor tions. No alloy was noted having a higher specific magnetism than pure iror Quenching an iron-carbon alloy from a high temperature reduces its specifi magnetism by a large but uncertain amount. The addition of silicon o aluminum to iron reduces the specific magnetism roughly in proportion t the amount added; but if carbon is present, silicon seems to neutralise i to some extent.

### 200. Comparisons of magnetic materials

(T. D. Yensen, Bulletin No. 72, Eng. Exp. Sta., Univ. of Ill., 1914)

| Material | Carbon content (per cent.) | Max. permeability | Flux density for max. permeability | Hysteresis loss in ergs per cu. cm. per cycle | | Coercive force for $\mathfrak{B}$ (max.) = 15,000 | Retentivity for $\mathfrak{B}$ (max.) = 15,000 | Resistivity at 20 deg. cent. (microhm-cm.) |
|---|---|---|---|---|---|---|---|---|
| | | | | $\mathfrak{B}$ (max.) = 10,000 | $\mathfrak{B}$ (max.) = 15,000 | | | |
| Swedish charcoal iron cut from plate. | 0.163 | 4,870 | 6,600 | 2,490 | 4,530 | 0.95 | 8,000 | 10.57 |
| Standard transformer steel. | ..... | 3,850 | 7,000 | 3,320 | 5,910 | 1.33 | 9,900 | 11.08 |
| Four per cent. silicon steel. | ..... | 3,400 | 4,300 | 2,260 | 3,030 | 0.88 | 5,400 | 51.15 |
| Swedish charcoal iron remelted *in vacuo*. | 0.008 | 10,350 | 7,000 | 1,290 | 2,640 | 0.48 | 11,200 | 10.30 |
| Electrolytic iron melted *in vacuo*. | 0.0125 | 12,950 | 6,550 | 1,060 | 1,990 | 0.34 | 9,940 | 9.96 |

**201. Formula for induction-permeability curve.** A. S. McAlliste has shown that the induction-permeability curve can be expressed with fair degree of accuracy by an equation of the form

$$\mu = 2{,}800 - 3.2\left[\frac{(7{,}500 - \mathfrak{B})^2}{10^5}\right] \qquad (17$$

The constants in this equation hold for the ordinary grades of sheet iron between the limits $\mathfrak{B} = 0$ and $\mathfrak{B} = 15{,}000$, where $\mathfrak{B}$ is the maximum instantaneous value. The numerical constants take different values for cast iron cast steel, silicon steel, etc. See McAllister, "Alternating-current Motors," New York, 1909, p. 137.

**202. Permeability in weak fields.** Ewing gives the permeability in very weak fields, with values of $\mathfrak{H}$ less than unity, according to the following formula based on investigations by Baur.

$$\mu = 183 + 1{,}382\mathfrak{H} \qquad (18)$$

This applies to soft iron. Lord Rayleigh found for harder grades of iron

$$\mu = 81 + 64\mathfrak{H} \qquad (19)$$

Digitized by Google

The latter applies to hard-drawn iron wire; in another case the initial permeability was 87. The foregoing relationships are accounted for by the fact that the saturation curve is sensibly a parabola in its earliest stages, starting, however, with a finite inclination to the axis of $\mathfrak{I}$. For extremely feeble forces it is virtually an inclined straight line. See Ewing, J. A., "Magnetic Induction in Iron and Other Metals," London, 1900, 3rd rev. d., Chap. VI.

**203. Permeability of iron at high frequencies** has been investigated by E. F. W. Alexanderson and H. Pender (see "Magnetic Properties of Iron at Frequencies up to 200,000 Cycles," Trans. A. I. E. E., 1911, Vol. XXX, pp. 2433–2454). Mr. Alexanderson concluded that iron has practically the same permeability at 200,000 cycles as at 60 cycles, but the magnetic penetration is greatly reduced at high frequencies, on account of the excessive skin effect, which must be taken into full account. See Par. **164.**

**204. Heusler's alloys** are composed of copper, manganese and aluminum, and possess marked magnetic properties. The permeability increases with the addition of manganese until the proportions of manganese and aluminum are the same relatively as their atomic weights (Par. **422**). The maximum magnetisation obtained is about one-third of that of the best iron.* Copper serves apparently no other purpose than to make the alloy soft enough to be cast and handled, McTaggart* performed experiments on these alloys, varying the composition in many ways. The particular composition which exhibited the best magnetic properties contained 14.3 per cent. aluminum, 28.6 manganese and 57.1 per cent. copper.

Dr. Heusler, who discovered these alloys in 1901, stated that the most magnetic alloy contained 25 per cent. of manganese, 12.5 per cent. of aluminum, and 62.5 per cent. of copper, or in the respective proportions of their atomic weights. Also see tests made by Guthe and Austin, Bulletin of the Bureau of Standards, 1906, Vol. II, No. 2, and tests by Stephenson, Bulletin No. 47, Eng. Exp. Sta., Univ. of Ill., 1910.

**205. Electron theory of magnetism.** Mr. E. H. Williams has written an extended monograph on this subject, which is published as Bulletin No. 62, Univ. of Ill., Eng. Exp. Sta., 1912, and contains a bibliography of the important works up to that date. Also see Chap. XI of Ewing's "Magnetic Induction in Iron and Other Metals."

## CORE LOSSES

**206. Total core loss** is composed of two elements, hysteresis and eddy-currents. These two losses follow different laws, briefly set forth in Sec. 2. The loss may be stated in terms of total energy per unit volume per cycle; or it may be stated in terms of power loss per unit weight of material at some stated frequency. The effect of wave-form is discussed in Par. **210** and **211.**

**207. Values of hysteresis coefficient for different materials**
(M. G. Lloyd)

| Material | $\eta$ | Authority | Material | $\eta$ | Authority |
|---|---|---|---|---|---|
| Hard tungsten steel | 0.058 | Steinmetz | Soft machine steel | 0.009 | Foster |
| | | | Annealed cast steel | 0.008 | Foster |
| Hard nickel | 0.039 | Steinmetz | No. 36 iron wire | 0.005 | Lloyd |
| Hard cast steel | 0.025 | Steinmetz | Ordinary sheet iron | 0.004 | Lloyd |
| Magnetic iron ore | 0.020 | Steinmetz | Pure iron | 0.003 | Gumlich |
| Forged steel | 0.020 | Steinmetz | Heusler alloy II | 0.0024 | Gumlich |
| Two-mil steel wire | 0.016 | Lloyd | Soft iron wire | 0.002 | Foster |
| Cast iron | 0.013 | Steinmetz | Annealed iron sheet | 0.002 | Lloyd |
| Soft nickel | 0.013 | Steinmetz | Ingot iron | 0.0016 | Lloyd |
| Cast steel | 0.012 | Steinmetz | Best annealed sheet | 0.0010 | Lloyd |
| Cobalt | 0.012 | Steinmetz | Silicon steel sheet | 0.0010 | Lloyd |
| Heusler alloy I | 0.012 | Gumlich | Silicon steel | 0.0009 | Gumlich |
| Electrolytic iron | 0.009 | Schild | Best silicon steel | 0.0006 | Lloyd |

See Loyd, M. G., "Magnetic Hysteresis," *Journal of the Franklin Institute*, July, 1910, pp. 1–25.

* McTaggart, H. A. Univ. Toronto Studies, Papers from Phys. Lab., 1908, No. 23.

**208. Hysteresis coefficients** in Steinmetz's formula $W_h = \eta f B^{1.6}$ are given in Par. **207** (Lloyd, M. G., "Magnetic Hysteresis," Journal of the Franklin Institute, July, 1910, pp. 1–25). In this formula $W_h$ is the loss in ergs per cu. cm. per sec., $f$ is the frequency in cycles per sec., $\mathfrak{B}$ is the maximum induction and is here 10,000 gausses, and $\eta$ is the hysteresis coefficient. The exponent of $\mathfrak{B}$, which is 1.6, departs widely from this value at very low and very high densities.

**209. Total core losses for sheets** are given in Fig. 29. Lloyd and Fisher give the following total core losses, in watts per lb. at 60 cycles and 10,000 gausses, for No. 29 gage (3.57 mm.): unannealed, 3.18 to 4.76; annealed, 1.25 to 2.36; silicon steel, 0.665 to 1.06. See *Trans.* A. I. E. E., 1909, Vol. XXVIII, p. 465. Also see Sec. 7, Par. **214.**

**210. Effect of wave form upon hysteresis loss.** Dr. M. G. Lloyd, in his paper entitled "Dependence of Magnetic Hysteresis upon Wave Form" (Bulletin of the Bureau of Standards, Vol. V, No. 3, Feb. 1909, pp. 381–411), reached the following conclusions.

"For a definite maximum value of the flux density, the hysteresis is greater with a flat wave of flux, but the effect is small, and from the industrial standpoint negligible, even with very distorted waves. If, however, the wave of flux is dimpled, the hysteresis may be much increased.

"The hysteresis determined by the ballistic method may be smaller than that which obtains with the use of alternating current, but the differences are small.

"The separation of hysteresis and eddy-current losses by means of runs at two frequencies, using the Steinmetz formula, is not accurate, but is a close approximation when the sheets are thin."

**211. Effect of form-factor upon the iron loss** was investigated by Dr. M. G. Lloyd (see "Effect of Wave Form upon the Iron Losses in Transformers," Bulletin of the Bureau of Standards, Vol. IV, No. 4, 1907; also Reprint No. 88), who reached the following conclusions.

"With a given effective electromotive force the iron losses in a transformer depend upon the form-factor of the e.m.f., and vary inversely with it. By proper design of the generator supplying transformers, the iron losses may be reduced to a minimum."

**212. Effect of unsymmetrical periodic cycles on hysteresis loss.** Mr. M. Rosenbaum in a paper entitled "Hysteresis Loss in Iron, Taken Through Unsymmetrical Cycles of Constant Amplitude," before the I. E. E. (see *Jour.* I. E. E., Mar., 1912), presented the following conclusions.

"It is seen that the hysteresis loss increases very appreciably as direct-current magnetization is superposed on the alternating flux. This phenomenon manifests itself in practice in inductor alternators and static balancers. In some kinds of inductor alternators the flux does not reverse, but oscillates between positive maximum and positive minimum values, thus the iron loss per cu. cm. is much greater in inductor alternators than in the ordinary type for the same change of flux in the armature coil. In static balancers this effect also takes place where the direct-current magnetization is not neutralized. It is therefore important, if high efficiency be aimed at, to neutralise the direct-current flux."

## SHEET GAGES

**213. Two systems of gaging sheets** are in use, the U. S. Standard Gage and the Decimal Gage. These two gages are fully covered in the two succeeding paragraphs. Also see Par. **30.**

**214. An act establishing a standard gage for sheet and plate iron and steel.** *Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled,* That for the purpose of securing uniformity, the following is established as the only standard gage for sheet and plate iron and steel in the United States of America, namely: (See Par. **215.**) And on and after July 1, 1893, the same and no other shall be used in determining duties and taxes levied by the United States of America on sheet and plate iron and steel. But this act shall not be construed to increase duties upon any articles which may be imported.

Sec. 2. That the Secretary of the Treasury is authorized and required to prepare suitable standards in accordance herewith.

Sec. 3. That in the practical use and application of the standard gage hereby established a variation of 2.5 per cent. either way may be allowed.

Approved, March 3, 1893.

**216. Standard decimal gage** for sheet iron and steel adopted by the Assoc. of Amer. Steel Manufacturers and the Amer. Railway Master Mechanics Assoc. is based on the following standard thicknesses, expressed in in.

| | | | | | | | |
|---|---|---|---|---|---|---|---|
| 0.002 | 0.012 | 0.022 | 0.040 | 0.065 | 0.090 | 0.135 | 0.220 |
| 0.004 | 0.014 | 0.025 | 0.045 | 0.070 | 0.095 | 0.150 | 0.240 |
| 0.006 | 0.016 | 0.028 | 0.050 | 0.075 | 0.100 | 0.165 | 0.250 |
| 0.008 | 0.018 | 0.032 | 0.055 | 0.080 | 0.110 | 0.180 | ..... |
| 0.010 | 0.020 | 0.036 | 0.060 | 0.085 | 0.125 | 0.200 | ..... |

The decimal system, denoting the thickness in thousandths of an inch, was endorsed by the A. S. M. E. Committee on Standard Thickness Gage for Metals. The weights are usually calculated on the basis of 480 lb. per cu. ft. for iron and 490 lb. for steel.

## COMMERCIAL SHEETS

**217. Electrical sheets** is the trade term for iron and steel sheets used in the manufacture of punchings for laminated cores or magnetic circuits.

**218. Grades.** There are usually but two, or at the most three, grades of commercial sheets. The ordinary grade is a soft or low-carbon steel, used extensively for laminated rotors and stators in electrical machinery. The special grade is a silicon steel, which has low core losses and is non-aging, used extensively for transformers.

**219. Data on American Sheet and Tin Plate Company's commercial sheets**

| | Regular dynamo and motor sheets | Special dynamo and motor sheets | Transformer sheets |
|---|---|---|---|
| Grade of steel (open hearth) | Soft | Soft | 4% silicon |
| Specific gravity, in sheets | 7.79 | 7.72 | 7.5 |
| Tensile strength, parallel to grain | 48,000 | 52,000 | 96,000 |
| Yield point, parallel to grain | 30,000 | 35,000 | 29,000 |
| Elong. in 8 in., parallel to grain | 21% | 25% | 2.4% |
| Tensile strength, transverse to grain | 55,000 | 61,000 | 102,000 |
| Yield point, transverse to grain | 33,000 | 38,000 | 22,000 |
| Elong. in 8 in., transverse to grain | 22% | 19% | 2.1% |
| Resistivity, microhm-cm | 8 to 12 | 15 to 18 | 40 to 50 |
| Hysteresis loss at $\mathfrak{G}=10{,}000$ in ergs per cu. cm. per cycle. | 4042 | 3336 | 1796 |
| Hysteresis coefficient | 0.001609 | 0.001328 | 0.000715 |

The tensile tests given above represent only a few tests and consequently are not average results. On Regular Dynamo and Motor Sheets, the Bureau of Standards obtained the following results, with No. 16 gage; tensile strength, 62,000 lengthwise and 63,000 crosswise; yield point, 42,000 lengthwise and 43,000 crosswise; elongation, 23 per cent. lengthwise and 28 per cent. crosswise.

The Regular and Special Dynamo and Motor grades are free from hardness and brittleness and there is no difficulty in shearing or punching them. The Transformer grade is generally harder than the ordinary grades, and in material having the lowest iron losses there is usually more or less brittleness. Generally speaking, there is no difficulty in shearing it and not much difficulty in punching it.

The Regular Dynamo and Motor grade is largely used in the construction of laminated poles and intermittently operated electrical apparatus. The Special Dynamo and Motor grade is used in high-efficiency dynamo and motor

Digitized by Google

rotors and stators. The Transformer grade is used very extensively in transformer cores.

Curves of average induction, permeability and hysteresis in these three grades are given in Figs. 20 to 25.

**220. Aging of sheets.** The American Sheet and Tin Plate Company reports the following results of aging tests on their commercial sheets (Par. 219). Exposure to a temperature of 100 deg. cent. for 30 days resulted (on

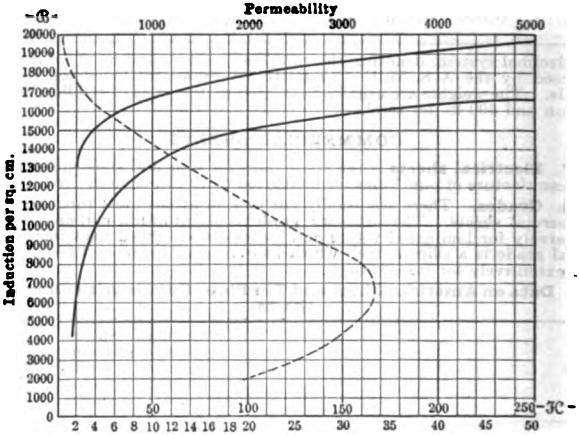

FIG. 20.—Average induction and permeability curves, "Regular Dynamo and Motor Sheets" (A. S. & T. P. Co.).

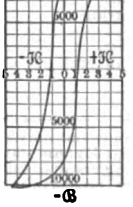

FIG. 21.—Average hysteresis loop, "Regular Dynamo and Motor Sheets" (A. S. & T. P. Co.).

the average of a number of samples of each grade) in a small increase in the iron loss (not exceeding 10 per cent.) in the Regular grade, a very slight increase in the iron loss of the Special grade, and a slight decrease in the iron loss of the Transformer grade.

**221. Effect of mechanical working on sheets.** The only working the material receives is punching and compression in the finished core. The

Digitized by Google

effect of punching is to deteriorate the magnetic properties, which can be removed by subsequent annealing, but if the cutting edges are sharp the effect is very small.

**222. Data on Follansbee steel sheets** are given in Figs. 26 to 28. Normal induction curves are shown in Fig. 26. Curves of total core loss are given in Figs. 27 and 28, all data being supplied by Follansbee Brothers Company.

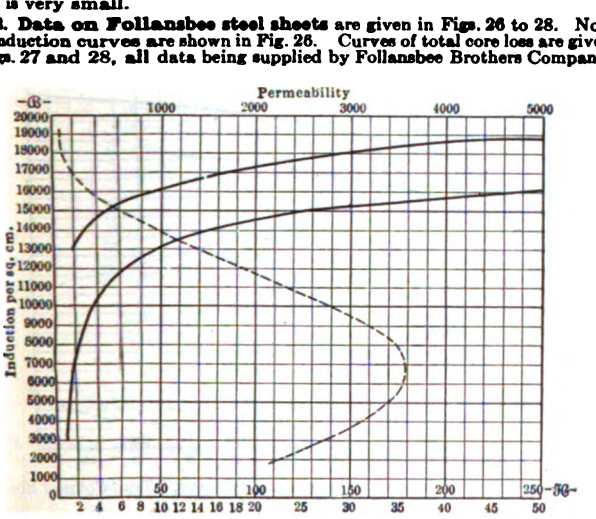

FIG. 22.—Average induction and permeability curves, "Special Dynamo and Motor Sheets" (A. S. & T. P. Co.).

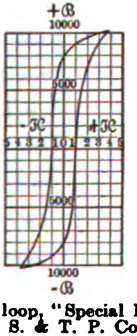

FIG. 23.—Average hysteresis loop, "Special Dynamo and Motor Sheets" (A. S. & T. P. Co.).

Both grades, carbon steel and silicon steel, are made by the basic open-hearth process. Further data may be obtained from articles by J. G. Homan in the *Electrical World*, Sept. 7, 1912, pp. 501–502, and the *Iron Age*, Jan. 2, 1913.

**223. Stalloy** is the trade name for a commercial transformer steel. Hamlen and Rossiter (*Electrician* (London), Nov. 3, 1911) found the maximum permeability to be as follows: unannealed, 3,100 at ℌ = 4,500; annealed, 4,200 at ℌ = 7,000. Hysteresis loss, 2,500 ergs per cu. cm. per cycle at ℌ = 10,000.

## MAGNET STEEL

**225. Desired characteristics in permanent magnets** are maximum retentivity, coercive force, and permanence or non-aging characteristic. These characteristics are best obtained in carbon steel and certain alloy steels hereafter mentioned.

Digitized by Google

**226. Magnet steel** usually contains about 3 to 7 per cent. of tungsten and 0.50 to 0.70 per cent. of carbon. The average tungsten content is about 5 per cent. If quenched in water from a temperature of about 800 deg. cent. it will retain its magnetism better than carbon-steel. The addition of about 0.50 per cent. of chromium will increase the permanency, but decreases the magnetic force. Also see Sec. 5.

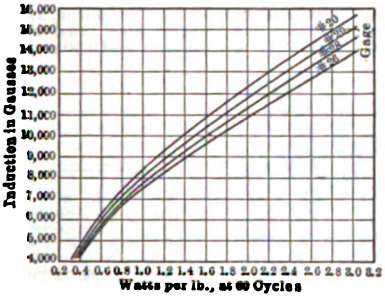

FIG. 27.—Total core loss in Follansbee improved electric steel sheets.

**227. Carbon magnet steel** is a high-carbon steel, and must be hardened by quenching after it has been forged and machined to shape. Fig. 30 shows the normal saturation curve and the hysteresis loop of a glass-hard pianoforte steel wire (Ewing, J. A. "Magnetic Induction in Iron and Other Metals;" London, 1900; 3rd rev. ed., pp. 83, 84). The maximum permeability in Fig. 30 is only 118. For information relative to the effect of

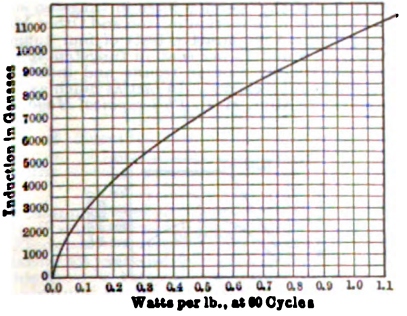

FIG. 28.—Total core loss in No. 29 gage (0.014 in.) Follansbee transformer steel.

different degrees of temper on the retentiveness see Bulletin No. 14, by Barus and Stronhal, U. S. Geological Survey, 1885.

Extensive experiments by G. Mars (*Stahl und Eisen*, 1909, Vol. XXIX, p. 1769) indicate that retentivity is a function of the hardness and composition of the metal. Fig. 31 shows relations between carbon content, hardness and

Digitized by Google

retentivity of carbon steel. The hardness tests were made with a 10-mm. Brinnell ball and a pressure of 3,000 kg. The retentivity increases with the carbon content and hardness up to a point where further increase in carbon is not accompanied by increase in hardness, then the retentivity decreases due to displacement of effective iron by the carbon. Similar experiments with various alloy steels give results shown in Par. **230.**

**228. Tungsten magnet steel** ordinarily contains about 5 per cent. of tungsten. One satisfactory magnet steel analysed 5.47 per cent. of tungsten, 0.57 per cent. of carbon, 0.18 per cent. of silicon, and 0.26 per cent. of manganese. Tungsten-vanadium magnet steel analyses about 7.00 per cent. of tungsten, 0.30 per cent. of vanadium, and 0.60 per cent. of carbon.

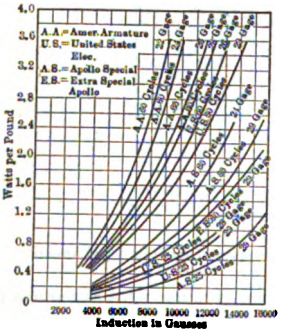

FIG. 29.—Curves of total core losses in electrical sheets.

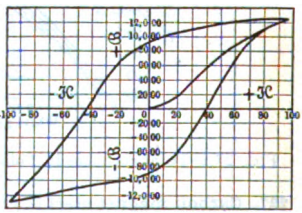

FIG. 30.—Hysteresis loop of glass-hard steel wire.

The addition of tungsten to steel increases the coercive force, and according to Hopkinson, the value of the coercive force in tungsten steel may exceed 50 (Ewing, J. A. "Magnetic Induction in Iron and Other Metals;" London, 1900; 3rd rev. ed., p. 83). Comparative tests of four tungsten steels containing respectively 3, 6, 8 and 12 per cent. of tungsten, quenched from 900 deg. cent., showed remarkably similar results and indicated that a high percentage of tungsten is unnecessary. In fact as much as 12 per cent. may produce inferior results (see Moir, M. B. *Philosophical Magazine*, Nov., 1914). Also see Sec. 5.

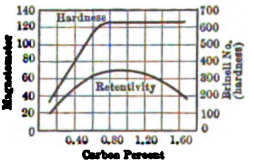

FIG. 31.—Hardness and retentivity of carbon-steel.

**229. Chrome magnet steel.** According to Hopkinson the addition of chrome to oil-tempered steel may increase the coercive force to as much as 40 (see *Philosophical Transactions*, 1885). Chrome-steels containing upward of 8 per cent. of chromium possess superior permanency compared with tungsten steels, but are inferior in magnetic intensity (see Moir, M. B. *Philosophical Magazine;* Nov., 1914).

**230. Composition and hardening temperature for maximum retentivity**
(O. A. Kenyon; 3rd edition, Standard Handbook)

| Steel | Composition per cent. | | | | | Hardening temp. deg. cent. |
|---|---|---|---|---|---|---|
| | C | Si | Mn | W | Cr | |
| Carbon | 0.97 | 0.20 | 0.15 | ..... | ..... | 810 |
| Tungsten | 0.58 | 0.18 | 0.26 | 5.47 | ..... | 930 |
| Chromium | 1.05 | 0.15 | 0.24 | ..... | 1.62 | 750 |
| Chrome-tungsten | 1.22 | ..... | ..... | 0.96 | 1.23 | 760 |

**231. Non-magnetic steels.** Hadfield found the presence of large proportions (12 per cent.) of manganese in steel deprived the metal of nearly all of its susceptibility. Hopkinson found that a specimen of steel containing 25 per cent. of nickel was practically non-magnetic at ordinary temperatures, but after cooling to a very low temperature it became strongly magnetic and remained so upon returning to normal temperature. The self-hardening steels (see "Structural Materials," Sec. 4) are also practically non-magnetic. Any steel in the austenitic state is non-magnetic.

## BIBLIOGRAPHY

**232. The authoritative literature** on the magnetic properties of iron, steel and other metals is for the most part scattered through many books dealing primarily with other topics, and through the transactions of the leading engineering and scientific societies and the technical press. The following is a selected list of the more important works and sources.

EWING, J. A.—"Magnetic Induction in Iron and Other Metals." London, 1900, 3rd rev. ed.

STEINMETZ, C. P.—"Alternating-current Phenomena." McGraw-Hill Book Co., Inc., New York, 1908.

KARAPETOFF, V.—"The Magnetic Circuit." McGraw-Hill Book Co., Inc., New York, 1911.

PENDER, H.—"Principles of Electrical Engineering." McGraw-Hill Book Co., Inc., New York, 1911.

GRAY, A.—"Electrical Machine Design." McGraw-Hill Book Co., Inc., New York, 1913.

# INSULATING MATERIALS

## CLASSIFICATION

**233 Methods of classification.** Dielectrics may be classified in a number of ways: (a) physical grouping, under solids, plastics, liquids and gases; (b) according to working temperature limits; (c) according to the type of application.

**234. Classification of dielectrics according to heat-resisting properties.** Messrs. Steinmets and Lamme in their A. I. E. E. paper on "Temperature and Electrical Insulation" (1913, Vol. XXXII, p. 79) classify the usual insulating materials as follows, in three general classes.

*Class A.* This includes most of the fibrous materials, as paper, cotton, etc., most of the natural oil resins and gums, etc. As a rule, such materials become dry and brittle, or lose their fibrous strength under long-continued moderately high temperature, or under very high temperature for a short time.

*Class B.* This includes what may be designated as heat-resisting materials, which consist of mica, asbestos, or equivalent refractory materials, frequently used in combination with other supporting or binding materials, the deterioration of which, by heat, will not interfere with the insulating properties of the final product. However, where such supporting or binding materials are in such quantity, or of such nature, that their deterioration by heat will greatly impair the final product, the material should be considered as belonging to class A.

Digitized by Google

*Class C.* This is represented by fireproof, or heat-proof materials, such as mica, so assembled that very high temperatures do not produce rapid deterioration. Such materials are used in rheostats and in the heating elements of heating appliances, etc.

The temperature limits specified by the A. I. E. E. Standardization Rules (Sec. 24, Par. **188**) are as follows:

(*A*–1) Cotton, silk, paper and other fibrous materials, not so treated as to increase the temperature limit, 95 deg. cent.

(*A*–2) Same as *A*–1, but treated or impregnated, and including enameled wire, 105 deg. cent.

(*B*) Mica, asbestos or any other material capable of resisting high temperature, in which any class *A* material or binder, if used, is for structural purposes only, and may be destroyed without impairing the insulating or mechanical qualities, 125 deg. cent.

(*C*) Fireproof and refractory materials, no specified limit.

**235. Physical Classification of Dielectrics**

- Dielectrics
  - Solids
    - Natural: Gums and resins; Asbestos; Wood; Soapstone; Slate; Marble; Lava; Mica
    - Fabricated: Papers and sheets; Fabrics and yarns; Hard rubber; Synthetic resins; Molded compositions; Glass; Vitrified materials
  - Plastics: Caoutchouc; Gutta percha; Pitches; Asphalts; Waxes; Compounds
  - Liquids
    - Used as such: Mineral oil; Animal oil; Vegetable oil
    - Solidified on application: Varnish; Shellac; Paint; Enamel; Japan
  - Gases: Atmospheric air; Hydrogen; Nitrogen; Carbon dioxide

**236. Classification of dielectrics according to type of application.** Under this classification can be named: (1) Wire insulation; (2) cable insulation; (3) insulating supports, combining dielectric properties with mechanical strength; (4) coil and slot insulation for electrical apparatus and machinery; (5) insulating sheets, slabs and barriers; (6) molded insulation, shaped under the application of heat and mechanical pressure; (7) impregnating and filling compounds; (8) superficial paints and varnishes; (9) fluid insulators; (10) gaseous insulators.

**237. Use of trade names** in connection with insulating materials has unfortunately become very common. On account of the great number of such names no attempt has been made to state or define them all. Wherever feasible, insulating materials have been grouped and described in accordance with a rational classification, and adhering if possible to the natural or descriptive name of each thing instead of its trade name.

## DISCUSSION OF PROPERTIES

**238. Desirable characteristics of dielectrics** may be enumerated as follows, under four heads: (1) electrical, (2) mechanical, (3) thermal, (4) chemical.

**(1) Electrical**

(a) Great resistivity.
(b) Small surface leakage.
(c) Great disruptive strength.
(d) Desirable magnitude of dielectric constant depends upon types of application.
(e) Small dielectric absorption.
(f) Small dielectric hysteresis.
(g) Minimum power factor.
(h) Minimum temperature coefficients.

**(2) Mechanical**

(a) Great tensile strength.
(b) Great shearing strength.
(c) Great compressive strength.
(d) Desirable magnitude of modulus of elasticity depends upon type of application.
(e) Desirable degree of hardness—ditto (d).
(f) Not brittle.
(g) Dense non-porous structure.
(h) Non-hygroscopic.
(i) Readily workable.

**(3) Thermal**

(a) Large specific heat.
(b) Small thermal resistivity.
(c) Small coefficient of expansion.
(d) High softening temp.
(e) High melting point, for solids.
(f) High boiling point and low freezing point, for liquids.
(g) Low viscosity.

**(4) Chemical**

(a) Stability.
(b) Insoluble in acids, alkalies and oils.
(c) High flash point.
(d) High fire point.

**239. Insulation resistance** is separable into two components, volume resistivity and surface resistivity. The leakage path through the substance or interior of the dielectric is electrically in parallel with the surface leakage path composed of a film of moisture or oil (with the frequent addition of dust or foreign matter) on the surfaces of the dielectric. For exhaustive discussion of the characteristics of insulation resistance and the insulating properties of dielectrics see the following:

Evershed, S. "The Characteristics of Insulation Resistance;" *Jour.* I. E. E., 1913.

Curtis, H. L. "Insulating Properties of Solid Dielectrics;" Scientific Paper No. 234, Bureau of Standards, 1915.

**240. Volume insulation resistance** of dielectrics is dependent upon the resistivity, usually expressed as volume resistivity in ohm-cm., or megohm-cm. for greater convenience. Practically all dielectrics have a negative **temperature coefficient**, or decreasing resistance with rising temperature. When the volume resistivity becomes very high, on the order of $10^{13}$ ohm-cm., the dielectric absorption current is likely to be of sufficient relative magnitude to influence the observed value of volume resistivity unless sufficient time is allowed for complete electrification. In the case of two materials having a resistivity of $10^{17}$ ohm-cm., hard rubber and fused quarts, the apparent resistivity under continuous electrification increases for a long time.

For most practical cases, however, that portion of the leakage current which flows through the body of the dielectric is negligible in comparison with the portion which flows through the surface film. But when the volume resistivity is less than $10^{14}$ ohm-cm. and when the insulator is placed in an atmosphere having a humidity of less than 25 per cent., the greater part of the current may flow through the body of the insulator.

In porous materials or those containing appreciable moisture, such as slate and marble, the volume resistivity decreases somewhat with increase of applied voltage. In all such cases the volume resistivity increases rapidly as the moisture is dried out.

The effective resistance with alternating currents is usually less than with continuous currents, and decreases progressively as a rule with increase in frequency, owing to dielectric energy losses (Par. 251).

Digitized by Google

**241. Surface insulation resistance.** The surface conductivity is the reciprocal of the surface resistivity, and the **surface resistivity** is the resistance between two opposite edges of a surface film which is 1 cm. square. Since for most materials under ordinary conditions of humidity the surface resistivity is much lower than the volume resistivity, the resistance per centimeter length between two linear conductors 1 cm. apart, pressed upon the surface of a slab of the material, is approximately equal to the surface resistivity.

The relationship between surface resistivity and humidity, for a number of different materials, is given in Fig. 32. These curves are generally typical of solid dielectrics. The surface resistivity is often a million fimes as great at low humidity as at high humidity. Measurements made on various molded compositions at the Bureau of Standards (Scientific Paper No. 234) gave values ranging from $10^{10}$ to $10^{17}$ ohm-cm. (between opposite edges of a film 1 cm. square), at 22 deg. cent.

FIG. 32.

**242. Dielectric constant** is defined in Sec. 2. The customary medium of reference is almost universally dry air at normal temperature and pressure. For most materials the temperature coefficient is positive, but for india-rubber it appears to be negative at ordinary temperatures. The coefficient for celluloid at 15 deg. cent. is approximately 0.005 per deg. cent., whereas for mica it is about 0.0006.

**243. Dielectric absorption** is the term applied to the apparent soaking up of electric charge within the body of a dielectric when the electric stress is prolonged for an appreciable time. In other words, it requires appreciable time for the dielectric to become fully saturated with electric charge or displacement, when a steady stress is applied. In some materials this phenomenon is marked, while in others it is slight. Due allowance should be made for it, however, in certain classes of measurements, notably insulation resistance.

**244. Dielectric strength,** usually expressed in volts or kilovolts (kv.) per mil or per mm.,* is a property which it is impossible to determine with high precision, and which is affected by numerous variables such as the size and shape of the test electrodes, the time rate at which the test voltage is raised to the disruptive point, the order of frequency of the test voltage and the thickness of the test specimen. Furthermore, disruptive discharge requires not merely a sufficiently high voltage, but a certain minimum amount of energy. There is no accepted standard apparatus or method for testing dielectrics, and hence the results obtained by different investigators are comparable only as to general order of magnitude, if at all. Moreover the probable error in measurements of disruptive strength is unusually large and any one set of observations is likely of itself to be in error by as much as plus or minus 10 to 20 per cent. Consequently the values of disruptive strength stated in this section are to be considered as purely approximate and not accurately comparative.

**245. The factors affecting dielectric strength** may be stated as follows; internal or external heating, chemical change, absorption of moisture,

* 1 volt per mil = 39.4 volts per mm.
1 volt per mil = 0.394 kv. per cm.
1 volt per mm. = 0.0254 volt per mil.
1 kv. per cm. = 2.54 volts per mil.

Digitized by Google

nature of surrounding medium, size and shape of test electrodes, thickness of test specimen, time rate of applying the disruptive voltage, whether continuous or alternating test pressure is employed, and order of magnitude of the test frequency.

**246. Effect of size of electrodes.** Farmer concluded from his tests that the average dielectric strength of insulating materials in *thin* sheet form is materially higher with small electrodes than with large ones; upon making the electrodes very small, such as needle points, however, the dielectric strength apparently decreases again. See Farmer, F. M., "The Dielectric Strength of Thin Insulating Materials;" *Trans.* A. I. E. E., 1913, Vol. XXXII, pp. 2097 to 2131. Also see Franklin, W. S., "Dielectric Stresses from the Mechanical Point of View;" *Jour. Franklin Inst.*, 1913.

**247. Effect of thickness of test specimen.** It is comparatively rare to find an insulating material whose dielectric strength varies uniformly with its thickness. In the case of fibre, for example, the disruptive strength increases very slowly with increasing thickness. On the other hand, the disruptive strength of multiple layers of glass with intervening oil films is nearly proportional to the thickness. A law was proposed by Baur which can be expressed $E = kl^{\frac{2}{3}}$, where $E$ is the disruptive voltage, $l$ is the thickness of the dielectric and $k$ is a constant; in other words, the disruptive voltage varies as the two-thirds power of the thickness. This law is a rough guide for some materials. Another law proposed by Walter, for air, is $E = a + bl$, where $a$ and $b$ are constants and $l$ is the thickness; this law holds for needle gaps from 50 to 450 mm. under ordinary pressures and temperatures.

**248. Lamination.** Hendricks* states that a finely laminated structure improves the dielectric strength. This is partly explained as follows: weak spots in successive layers very rarely coincide in position, rupture at some local internal point may be confined to one lamination, and thin materials are in general superior in point of electric and mechanical unit strength.

**249. Effect of frequency.** There is usually considerable difference between disruptive strengths as determined by alternating e.m.fs. and by continuous e.m.fs. In the case of continuous e.m.fs. there is much less internal heating than there is with alternating e.m.fs. Disruptive strengths of solid dielectrics measured with continuous e.m.fs. are about one and one-half to two times the strengths measured with alternating e.m.fs. under like conditions. When the order of frequency is increased from commercial power frequencies to those representative of high-frequency high-power surges, say 200,000 cycles, there is reason to believe that the disruptive strength is reduced. Creighton has shown that this is the fact in the case of porcelain (see *Proc.* A. I. E. E., May, 1915, p. 819, Fig. 29), where disruptive values at very high frequency were on the order of 60 to 80 per cent. of the 60-cycle values.

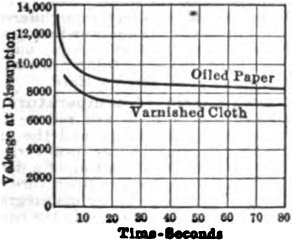

FIG. 33.—Typical curves of disruptive voltage with respect to interval required for puncture.

**250. Effect of the time element** in applying the disruptive pressure is pronounced. For very brief periods dielectrics will withstand much greater potentials than for longer periods. This is apparently a consequence, in part at least, of the fact that disruptive discharge requires a certain minimum amount of energy in each instance. Thus the disruptive energy required in the case of oil is about 30 times that required for air. It is characteristic of oil and of materials impregnated with oil that the dielectric strength is greater for instantaneous or very brief applications of stress than it is under prolonged stress. The brief time interval required to energise the dielectric

* Hendricks, A. B., Jr. "High-tension Testing of Insulating Materials;" *Trans.* A. I. E. E., 1911, Vol. XXX, p. 167.

Digitized by Google

before breakdown occurs is sometimes referred to as the dielectric spark lag. A good illustration of the comparative effects of slow versus fast rate of application of the disruptive voltage is given by Creighton for porcelain (see *Proc.* A. I. E. E., May, 1915, p. 818, Fig. 28). Also see Hayden and Steinmetz, "Disruptive Strength with Transient Voltages;" *Trans.* A. I. E. E., 1910, Vol. XXIX, pp. 1125 to 1158. Fig. 33 shows typical curves (plotted from Rayner's 1912 paper, *Jour.* I. E. E.) of disruptive voltage with respect to the time required for puncture.

**251. Dielectric hysteresis** is a form of energy loss in dielectrics, and is independent of any loss due to pure conduction. The latter loss is expressed by $gE^2$, where $g$ is the total conductance in mhos of a given body of dielectric and $E$ is the impressed difference of potential in effective volts, the power loss given thereby being expressed in watts. The **static component** of dielectric hysteresis probably is proportional to the 1.6th power of the maximum dielectric flux density. The **viscous component** of dielectric hysteresis follows the square law. The latter component is probably the predominating one, since experimental evidence* from condenser tests with alternating currents goes to show that the angle of phase difference due to hysteresis is a constant, for any particular condenser. It follows from this that the power loss in the dielectric is proportional to the square of the flux density and the square of the frequency, which corresponds to the viscous component of hysteresis. As a rule these electrostatic hysteresis losses in a condenser are much smaller than the losses occasioned by magnetic hysteresis and are rather difficult to measure. Frequently they amount to no more than a fraction of 1 per cent. of the volt-ampere input of the condenser, at frequencies from 25 to 125 cycles. See Rayner, E. H., "High-voltage Tests and Energy Losses in Dielectrics;" *Jour.* I. E. E., 1912, Vol. XLIX, No. 214, pp. 3 to 89; also see Fleming and Dyke, "On the Power-factor and Conductivity of Dielectrics;" *Jour.* I. E. E., 1912, Vol. XLIX, No. 215, pp. 323 to 431.

**252. Dielectric power-factor.** When a dielectric is subjected to a periodic alternating e.m.f. less than the disruptive value there is a loss or expenditure of energy within the dielectric from two causes: (1) the leakage conduction current, (2) the dielectric hysteresis. Consequently, the volt-ampere input to the dielectric, instead of having a zero power-factor as in the case of the ideal dielectric of infinite resistance and zero hysteresis, has a power-factor of finite value but usually small magnitude. This total dielectric loss may, in some cases, have considerable importance. Fleming and Dyke* made tests on eleven different materials at 920, 2,760 and 4,600 cycles, and found that the power-factor was less than 1 per cent. in the case of dry Manila paper, paraffin wax, mica, ebonite, pure india-rubber, vulcanized india-rubber and sulphur; about 2 per cent. for glass and gutta percha; and 8 per cent. for dry slate.

**253. Effects of temperature.** If a dielectric contains moisture, the application of heat will reduce the moisture content and simultaneously increase the resistivity and the disruptive voltage. In the case of a thoroughly dry substance, however, increase of temperature has the reverse effect. Prolonged heating of a dielectric, if in excess of the safe or conservative limit of working temperature, is injurious and tends to hasten the breakdown of the material by disintegration or chemical change, and ensuing disruptive failure. Except in the case of fireproof and refractory materials, the working temperature is a most important factor in determining the life of insulation. See Par. **234** and also see the temperature limits specified in the Standardization Rules of the A. I. E. E., Sec. 24, Par. **187** to **200**.

## SOLID NATURAL MATERIALS

**254. Asbestos** is a mineral fibre comprised of hydrous silicate of magnesia, which melts at a temperature in the range from 1,200 to 1,300 deg. cent. It is useful as an insulating material because of its heat-resisting qualities, and is fabricated into boards, paper, tape, etc., frequently in combination with a binder to make it stronger mechanically and less absorbent of moisture. It is not inherently a good insulator, and for this reason is frequently mixed with other fibres or loading material to impart greater strength, higher insulation and better finish. The commercial varieties of asbestos often

* Steinmetz, C. P. "Alternating-current Phenomena;" New York, McGraw-Hill Book Co., Inc., 1908· 4th ed., pp. 212 and 213.

Digitized by Google

contain iron and other impurities, making it almost useless as an electrical insulator. Asbestos is an excellent thermal insulator. Its electrical resistivity is on the order of $16 \times 10^6$ ohm-cm.; disruptive voltage, 60 to 100 volts per mil; maximum working temperature, 500 to 600 deg. cent. When used for arc defectors in controllers, switches, etc., it is usually impregnated with a solution of silicate of soda and then subjected to heavy pressure.

Asbestos is frequently combined with magnesium carbonate, or with finely ground sponge, or with wool felt, as a thermal insulation for steam pipes; it is also mixed with cattle hair, for similar use, and known as asbestos hair felt. Asbestos is also extensively employed in the manufacture of molded compositions designed to withstand high temperatures.

**255. Chalk** is a fine-grained limestone of marine origin, composed of finely comminuted shells, particularly those of the foraminifera. The specific gravity may be as low as 1.8. A theoretically pure limestone is merely a massive form of the mineral calcite, consisting entirely of calcium (lime) carbonate, $CaO + CO_2 = CaCO_3$, or 56 per cent. CaO and 44 per cent. $CO_2$.

**256. Fire clay.** Clay is the term applied to fine-grained unconsolidated natural materials which possess plasticity when wet, but lose it on being heated and become hard. The specific gravity ranges between 1.5 and 2.2. The clays are composed essentially of silica and alumina, in a state of exceedingly fine subdivision, resulting from the decay of older rocks. Fire clay is the variety of clay which is most highly refractory, containing much silica and little lime, iron or alkalies. As an insulator it is applied in semi-liquid form and baked, after the conductors are imbedded. It is not affected by acids, oils or alkalies.

**257. Gums and resins.** The natural gums and resins such as caoutchouc, gutta-percha, pitch, etc., are seldom if ever employed for insulating purposes while in their native condition, but are treated, or mixed with other materials, or adulterated, in a great variety of ways. They form the bases or constituents of many different insulating compounds, but undergo numerous chemical or physical changes in manufacture.

**258. Ice.** The disruptive strength of ice is 11 kv. (max.) per cm.; dielectric constant, 86.4; resistivity, $7.2 \times 10^7$ ohm-cm. See Thomas, P., "The Dielectric Properties of Non-conductors;" *Jour. Franklin Inst.*, 1913, Vol. CLXXVI, pp. 283 to 301. According to Whittaker's Pocketbook, pure water has a resistivity of $7 \times 10^{12}$ ohm-cm.

**259. Ivory** has a resistivity at 22 deg. cent. of $2 \times 10^6$ ohm-cm.

**260. Kaolin** is a white china clay whose chief ingredient is the mineral kaolinite, and the latter has the chemical composition $H_2Al_2Si_2O_8 + 1H_2O$, or hydrous silicate of aluminum. Kaolin is highly refractory and is one of the principal materials employed in the manufacture of porcelain. It is sometimes employed for insulating purposes.

**261. Lava** is a mineral **talc**, which has the chemical composition $H_2Mg_3Si_4O_{12}$, or hydrated magnesium silicate, and is similar to soapstone, pumice and talc. It is slightly soluble in hydrochloric acid, but is not attacked by other acids or alkalies. While in the natural state it can be machined with the same facility as brass. It neither shrinks nor expands under the influence of moisture and has a very small coefficient of expansion.

After machining, it is baked at about 1,100 deg. cent. which renders it extremely hard. Its insulating resistance is high and according to tests made by the American Lava Co., its dielectric strength varies from 3,000 to 10,000 volts per mm., according to the thickness. See Par. **270** and **271**.

**262. Lavite** (also see lava) is a light buff or cream-colored insulating material invented and patented in 1885 by D. M. Steward. The manufacturers supply the following information: Density, 2.5 to 2.7; electrical resistivity, 500 to 2,500 megohm-cm.; disruptive strength, 200 to 250 volts per mil; modulus of rupture, 6,000 to 12,000 lb. per sq. in.; compressive strength, 20,000 to 30,000 lb. per sq. in.; compares with glass in hardness; not affected by temperatures up to 1,000 deg. cent.; unaffected by acids except aqua regia.

**263. Marble** is a limestone of the crystalline variety which will take a high polish and exhibit pleasing color effects. Its chief constituents are lime and magnesia, or their carbonates; it also contains water of formation and sometimes metallic veins. It is used very extensively for low-tension

Digitized by Google

switchboard panels. Its properties can be improved by treatment in molten paraffin wax or linseed oil, after all moisture has been expelled, but such treatment results in discoloration. The resistivity is on the order of $10^2$ to $10^4$ megohm-cm. and the disruptive voltage is in the vicinity of 50 to 100 volts per mil. See tests in Par. **266**.

**264. Mica** is generally recognized as the most superior insulating material known to the art, that which is imported from India being the best, the Canadian grades next and domestic varieties last. Either domestic or India mica is satisfactory for nearly all insulating purposes except for commutators, where it is too hard to wear down as fast as the copper bars. For the latter service Canadian amber mica is considered more satisfactory, being softer than the other grades. All grades of muscovite (white) mica are considered suitable for electric heating appliances. Mica sheets and washers are used in electrical apparatus and appliances in almost innumerable shapes. Cut mica in sheets becomes very expensive in the larger sizes, the largest commercial listed size being 8 in. by 10 in. On this account it is customary to build up larger sizes by connecting together thin layers of mica. Such manufactured mica plate takes a number of forms.

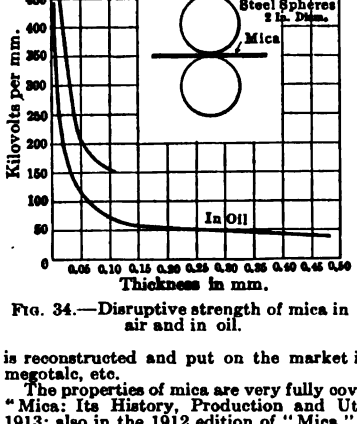

FIG. 34.—Disruptive strength of mica in air and in oil.

**265. Composition and properties of mica.** Mica is a refractory mineral constituted of the double silicate of alumina or magnesia, and potash or soda, combined with varying proportions of potash, soda and other impurities. Iron in excess colors it gray and black; magnesia tends to darken the color; aluminium and potassium silicates tend to make the mica transparent. Mica crystallizes in laminated form and may be split along its axis to sheets as small as 0.006 mm.

It has a high dielectric strength and is suitable to withstand high temperatures. However, in its natural state it is not flexible nor uniform, and permits large surface leakage; so that most mica is reconstructed and put on the market in the form of micanite, megomit, megotalc, etc.

The properties of mica are very fully covered in a publication by Zeitler, H, "Mica: Its History, Production and Utilization;" D. Jaroslaw, London. 1913: also in the 1912 edition of "Mica," by the Canadian Dept. of Mines. These sources were utilized in the preparation of the following table.

| Origin | Resistivity in $10^{12}$ ohm -cm. | Dielectric constant | Disruptive strength in volts per mm.* |
|---|---|---|---|
| Madras | 15 to 133 | 2.5 to 5.5 | 50,000 to 80,000 |
| Bengal | 7 to 118 | 2.8 to 4.7 | 40,000 to 120,00 |
| Canada | 0.44 to 22 | 2.9 to 3.0 | 80,000 |
| South America | 39 | 5.9 | 40,000 to 90,000 |

Fleming and Johnson give the dielectric strength, in sheets 2 to 3 mils thick, as about 2,000 volts per mil for amber mica and about 3,000 to 4,000 volts per mil for the white, ruby and soft green varieties; Fig. 34 shows the

* NOTE.—Test thickness, 0.3 mm.

Digitized by Google

results of tests made by Rayner at the National Physical Laboratory (*Jour. I. E. E.*, 1912, Vol. XLIX, No. 212). Power-factor at 920 cycles, 0.001. The density of mica is from 2.7 to 3.1. Specific heat, 0.206 to 0.208. It is not affected by heat until a temperature of several hundred degrees centigrade is reached, when the laminæ separate in the harder varieties and tend to disintegrate into small scales or flakes; amber mica is less affected. Melting-point, 1,200 to 1,300 deg. cent. It will withstand great mechanical pressure perpendicular to the plane of cleavage.

**266. Mica products.** Many products are manufactured from mica, including paper, cloth, plate and molded insulation. In some cases the strips of mica are mounted on paper or cloth, in alternate layers, using an insulating binder such as shellac. Molded products are usually made from ground mica mixed with a binder, and sometimes mixed with other insulating materials such as asbestos, or a gum or compound.

**267. Quartz** is a form of **silica** ($SiO_2$) occurring in colorless transparent hexagonal crystals, but sometimes yellow, brown, purple, green and other colors. It also occurs in crystalline masses of vitreous luster. Density, 2.65. Dielectric constant 4.3 to 5.1. The resistivity is from $10^{16}$ to $10^{17}$ ohm-cm. Silica is the principal constituent of glass. Quartz fibres of very small lateral dimensions are sometimes used for suspensions in delicate electrical instruments; such fibres have a tensile strength of about $10 \times 10^9$ dynes per sq. cm. Also see fused silica (Par. **278**).

**268. Slate** is a rock of clay composition, in which pressure has produced a very perfect cleavage, so that it may be split into thin tough plates. The principal constituents are silica and alumina, with small percentages of iron oxides, lime, magnesia, potash and soda. It frequently contains metallic veins, which make it worthless for electrical work. It is hygroscopic, in addition to containing water of formation, and is therefore far from an ideal insulator. The resistivity of a good grade of slate at normal temperature is of the order of $10^2$ to $10^4$ megohm-cm., and decreases rapidly at high temperatures; higher values of resistivity have been obtained with very dry specimens. The dielectric constant is between 6 and 7. Power-factor at 920 cycles, 0.086. The disruptive voltage for 1 in. of thickness is from 5,000 to 10,000 volts, or 5 to 10 volts per mil. See tests in Par. **269**. Specific heat, about 0.2; thermal conductivity, 0.0036 g-cal. per cm-cube per deg. cent. per sec. The density is from 2.7 to 2.9. Slate is a satisfactory insulator where a non-combustible, low-tension material having fair insulating properties is required. It is sometimes varnished or enamelled to keep out moisture.

**269. Puncture tests of Vermont slate and marble,*** made with flat circular brass electrodes 0.785 in. in diameter having slightly rounded edges, indicated values ranging from 50 volts to 100 volts per mil for marble (test pieces 14 in. square and about 1 in. thick) and roughly one-tenth of these values for slate. Blue marble was considered superior to white marble. Marked heating of the specimens was noted at or near the rupturing voltages, being less marked in the case of blue marble, and especially marked in slate; the test pieces were air dried in a warm room for several weeks before testing, but undoubtedly retained a certain amount of moisture. Corona or brush discharges were very noticeable during the tests, at pressures in the vicinity of the rupturing values.

**270. Soapstone** is a kind of soft stone, which is soapy or slightly oily to the touch. It is also known as **steatite**, or massive variety of **talc**, of grayish-green or brown color. It forms extensive beds and is mined for hearths, sink linings, etc. It is occasionally used for electrical insulation, in the form of slabs or barriers and will withstand very high temperatures. It is soft, not very strong, not affected by acids, oils or alkalies; can be machined, drilled and sawed, and absorbs moisture.

**271. Talc** is a hydrous magnesian silicate, $H_2Mg_3(SiO_3)_4$, containing when pure 63 per cent. of silica, 32 per cent. of magnesia and 5 per cent. of combined water. It has a specific gravity of 2.6 to 2.9. Soapstone and French chalk are varieties of talc; other varieties are used in making soap, paper, lubricants, etc. See Par. **261**.

* Report of the Vermont State Geologist, 1912, pp. 196 to 219.

Digitized by Google

**272. Wood** is used as an insulating material to a considerable extent. The varieties of wood employed are usually the hard woods, such as maple and hickory, impregnated with oil, paraffin wax, or clear air-drying varnish. The resistivity of paraffined wood, at 22 deg. cent. is of the following magnitude: mahogany, $4\times10^{13}$ ohm-cm.; maple, $3\times10^{10}$; poplar, $5\times10^{11}$; walnut, $0.09\times10^{10}$ to $1\times10^{10}$ (Scientific Paper No. 234, Bur. of Standards). The dielectric constant and the disruptive voltage are both dependent upon whether the electric stress is parallel or perpendicular to the grain. Parallel to the grain the dielectric constants of red beech and oak are between 2.5 and 4.8; perpendicular to the grain, 3.6 to 7.7.

In maple boiled in transformer oil under vacuum, dried under vacuum and boiled again at atmospheric pressure, the disruptive voltage along the grain, at 1 in. of separation, was 70 kv.; at 2 in. it was 90 kv.; across the grain, at 0.5 in., it was 60 kv.; at 1 in. it was 80 kv.; dielectric constant, at 20 to 25 deg. cent., across grain, 4.1. Well-dried wood should stand 10 kv. per in. without signs of burning or heating. It is extremely important that the wood should be well dried before impregnation, because it is very difficult to remove the moisture subsequently. When wood contains moisture it is a relatively poor insulator and the water contained in the cells conducts electrolytically. Wood treated with zinc chloride to protect it against decay has comparatively low resistivity; see *Electrical World*, 1911, Vol. LVII, p. 828. For curves of disruptive strength of maple see Hendricks, A. B., "High-tension Testing of Insulating Materials;" *Trans.* A. I. E. E., 1911, Vol. XXX, pp. 167 to 213.

## VITRIFIED MATERIALS

**273. Glass** is an insulating material in very extensive use, possessing high resistivity and dielectric strength at ordinary temperatures. The principal constituent is silica, ranging from 50 to 75 per cent. of the total contents; potash, soda, lead oxide and lime are also present, in various proportions. The resistivity at ordinary temperatures is on the order of $10^{13}$ to $10^{18}$ ohm-cm. and decreases with great rapidity as the temperature increases. Gray and Dobbie found that potash glass has higher resistivity than soda glass, and annealing increases the resistivity (*Proc.* Royal Soc., 1900, Vol. LXVII, p. 197). At very high temperatures glass becomes a fairly good conductor. Moisture readily condenses upon its surface and it has consequently a high surface leakage. It is also soluble in water to a slight degree and under weather exposure the surface tends to roughen. The dielectric constant ranges from about 5.5 to 10. The dielectric strength ordinarily ranges from 150 to 300 volts per mil, and is higher in very small thicknesses. At 920 cycles crown glass has an apparent resistivity of $17\times10^9$ ohm-cm.; dielectric constant, 6.60; power-factor, 0.018. Mechanically glass is unreliable and brittle; the tensile strength is uncertain and anywhere from 1,000 to 10,000 lb. per sq. in., with somewhat higher compressive strength. Coefficient of linear expansion, 0.000008 to 0.0000095 per deg. cent. Density 2.5 to 4.5. For information on glass manufacture see Rosenhain, W., "Glass Manufacture," D. Van Nostrand Co., New York.

**274. Porcelain.** The three principal constituents of electrical porcelain are feldspar, clay and silica. There are three feldspars: orthoclase, or potash feldspar, which is the most important; albite or indianite, which is soda feldspar; anorthite, or lime feldspar. The two clays used are ball clay, and china clay or kaolin. A standard mixture of these constituents for testing purposes is 20 parts feldspar, 50 parts kaolin and 30 parts quarts. The function of the feldspar is to act as a flux to unite the other constituents into a vitreous mass when fired. There are two processes of manufacture, the dry process and the wet process. For details on the manufacture and properties of electrical porcelain, see an exhaustive paper by E. E. F. Creighton, "Electrical Porcelain;" *Proc.* A. I. E. E., May, 1915, pp. 753 to 841. Also see Perrine, F. A. C., "Electrical Conductors;" D. Van Nostrand Co., New York, 1903; Chap. XIII.

**275. Dry-process porcelain** is manufactured by molding the moist raw mixture under high mechanical pressure and then vitrifying by the usual firing process. This grade of porcelain is usually very porous and consequently has a disruptive strength on the order of atmospheric air, or less. At or near disruptive pressures, however, it heats rapidly and is not suitable for high-voltage insulation. The safe dielectric strength is on the order of 1,000 volts.

Digitized by Google

**276. Wet-process porcelain** is made by mixing the raw ingredients with water. The mixture is placed in a filter press and the surplus water extracted, leaving a wet plastic cake. The cake is re-mixed in a pug mill to make it more homogeneous, then molded or jiggered into a blank of approximate final shape, and allowed to dry. When fairly dry it is turned in a lathe or tooled to final shape, dipped in the glazing bath and placed in the kiln preparatory to firing. The glazing mixture is the same as the porcelain except that it contains more flux, and thus melts at a temperature barely sufficient to vitrify the porcelain. The finished glaze is virtually a species of glass. During manufacture porcelain shrinks from 10 to 20 per cent. and much care is required to proportion the parts so that cracking will not result. The thickness is limited both by the shrinkage and the difficulty of obtaining satisfactory vitrification. High-voltage porcelain is made in all cases by the wet process.

**277. Properties of high-voltage porcelain.** The density is from 2.3 to 2.5. It is not affected by oils, acids or alkalies; the glaze is said by some authorities to be very slightly soluble in ordinary water. Unglazed porcelain should be non-hygroscopic and on immersion should not increase in density. A good rough test is to place a drop of ink on the porcelain and note whether it spreads or penetrates; alcohol solutions are still better. The linear expansion coefficient is from 4.5 to $6.5 \times 10^{-6}$ per deg. cent. The specific heat is 0.17 and the thermal conductivity is 0.045 per cent. of that of silver. The electrical resistivity of unglazed porcelain is on the order of $10^{14}$ to $10^{15}$ ohm-cm. at ordinary temperatures, and decreases very rapidly with increasing temperatures; at very high temperatures porcelain becomes a fair conductor, and is therefore unsuitable for electric furnaces.

The dielectric constant is from 4.4 to 6.8 with continuous e.m.f. and about 10 per cent. less at 50 cycles per sec. At low frequencies the disruptive voltage is about 30 kv. for a thickness of 0.1 in. and about 110 to 120 kv. for a thickness of 0.5 in. At frequencies of the order of 200,000 cycles the disruptive strength, for a thickness of 0.5 in., is on the order of 80 to 90 kv. and if the test voltage is applied rather slowly the disruptive strength varies in much smaller proportion than the thickness (see paper by Creighton mentioned below). In some cases mechanical stress has been observed to reduce the disruptive strength, but in other cases had little effect.

American porcelains have a tensile strength which is variously stated from 650 to 2,200 lb. per sq. in., with an average of about 1,400 lb. per sq. in. The compressive strength is about 10 times the tensile strength. Modulus of elasticity, 2,500,000 in-lb. European porcelains are generally reported as having a tensile strength of 4,500 to 6,500 lb. per sq. in. and a compressive strength of about 65,000 lb. per sq. in. The following references on porcelain are given for the convenience of those who wish more complete information.

**278. Silica.** The properties of **fused silica** are as follows: Resistivity at ordinary temperatures, on the order of $10^{14}$ to $10^{19}$ ohm-cm., decreasing rapidly at higher temperatures; dielectric constant, 3.5 to 3.6; dielectric strength, above 600 volts per mil; melting-point, 1,700 to 1,800 deg. cent.; coefficient of expansion, 0.0000006; density, about 2.07. Also see *Chemical Abstracts*, Vol. IV, p. 866, and Vol. VII, p. 3443.

**279. Tile.** Vitrified clay tile is very extensively used for underground conduits. Although it possesses very fair insulating properties, its use for this purpose is owing very largely to its immunity from corrosion and disintegration under sub-soil conditions and also its ability to withstand a great

Digitized by Google

range of temperatures without injury. As a rule, it is slightly absorbent, receiving as much as 3 or 4 per cent. of water, in some cases, in 24 hr. The puncture voltage, with a 0.6-in. (1.5 cm.) wall, after 24-hr. immersion, ranges from about 16,000 to 30,000 volts. It is not affected by arcs unless in direct contact with them, and in that event will be likely to melt locally and chip or fracture in the surrounding area in consequence of unequal heating and expansion.

**280. Vitreous enamel** consisting of opaque white glass is extensively used for coating iron resistor grids and imbedding the resistor wires, thus forming non-inflammable and highly fireproof devices capable of withstanding unusually high operating temperatures. Enamelled iron-ware is made extensively by the process of sprinkling powdered glass upon red-hot metal, whereupon the glass fuses and forms a continuous thin coating. The formulas used for compounding the glass are quite closely guarded as manufacturing secrets. What is desired is a thin, strong elastic coating which will expand and contract with temperature changes at as nearly as possible the same rate as iron.

## FIBROUS MATERIALS

**281. Cellulose** is the base of practically all fibrous insulating materials and is an organic compound composed of 48 per cent. carbon, 46 per cent. oxygen and 6 per cent. hydrogen. It is a carbohydrate of the formula $(C_6H_{10}O_5)_x$, similar in composition to starch. When pure it is a white amorphous mass; unsized, well-bleached linen paper is nearly pure cellulose. It has a resistivity on the order of $10^8$ to $10^{10}$ ohm-cm. at ordinary temperatures and a dielectric constant of about 3.9 to 7.5. All untreated cellulose materials break down at about 120 deg. cent. and should not be subjected to a maximum of more than 95 deg. cent. A safe operating limit is about 80 deg. cent.

**282. Untreated fibrous materials** are as a whole hygroscopic and are therefore relatively inferior insulating materials. They are nevertheless employed, some of them, to a great extent, but their use is very largely confined to conditions under which moisture is restricted or expelled. Their properties are greatly improved by treatment or impregnation.

**283. The impregnation of fibrous and asbestos products** with varnishes, gums, bakelite, etc., produces several results: First, the treating materials fill up the pores of the basic material and eliminate moisture; second, the dielectric strength is increased even where there is no moisture to be considered; third, most treating materials assist in producing smooth surfaces; fourth, the heat-resisting quality of the basic material is often increased, and, fifth, the filling up of the pores may in certain cases reduce the tendency to shrink. Incidentally the treating materials increase the heat conductivity of the insulation, resulting in better radiation.

**284. Paper** is manufactured from wood pulp, rags or plant fibre. The essential processes in manufacture are (1) the reduction of the raw material to the consistency of a thin pulp, by means of operations involving the use of chemicals and steam; (2) the running of this pulp upon a continuous sieve of fine mesh, which retains the fibres that become felted together; (3) the removal, drying and finishing of the felt so formed. Finished paper retains traces of the bleaching or coloring matter employed, and in addition frequently contains a certain amount of loading matter such as china clay, calcium sulphate and other inert mineral matter. A sising of vegetable or mineral solution is sometimes added to render the paper less porous and improve the surface.

The mechanical properties of paper are derived in large degree from the basic fibres employed in its manufacture; thus paper made from wood pulp is brittle and easily torn, whereas linen or Manila fibre produces a much tougher and stronger paper. Owing to its porosity paper is hygroscopic and normally contains from 7 to 12 per cent. of moisture. When thoroughly dry it has a very high resistivity, on the order of $10^{15}$ ohm-cm., but it easily absorbs water and when wet descends to the class of a poor conductor. The dielectric constant of dry paper is from 1.7 to 2.6. Dry Manila paper has a power-factor of about 0.007 at 920 cycles. The dielectric strength of various kinds of untreated paper, ranging in thickness from 1.8 to 28 mils, should average from 110 to 220 volts per mil; higher values are obtainable from extremely dry paper. The tensile strength will range from a few thousand up

Digitized by Google

to many thousand lb. per sq. in., depending upon the quality of fibre. The elongation at fracture is slight, about 2 or 3 per cent. For temperature limits see cellulose, Par. **281**. There are numerous varieties of insulating paper, such as rope paper, Japanese paper, Manila paper, whale-bone paper, fuller board, pressboard, etc., some of which are briefly mentioned in other paragraphs.

**285. Treated paper** is a clear dry paper impregnated with oxidised linseed oil, or a mixture such as oxidised oil and asphalt, or a gum-base varnish. Well-treated papers in thicknesses ranging from 6 to 12 mils break down at about 500 to 750 volts per mil. The Mica Insulator Co. gives disruptive voltages for Empire oiled papers, in thicknesses of 1.5 to 18 mils, ranging from 1,740 to 800 volts per mil; these values include condenser, rope, bond and cement paper and fuller board. The same manufacturer gives for rope paper treated with a compound of oxidised oil and asphalt, disruptive voltages ranging from 1,600 to 600 volts per mil, corresponding to thicknesses of 5 to 15 mils. According to Jona, the dielectric strength of impregnated paper cable insulation is from 200 to 250 volts per mil, and the dielectric constant is about 2.5 to 4. The value of the constant $k$ (see Par. **293**) for impregnated paper is usually between the extremes of 1,000 and 3,000.

**286. Bakelized paper**, known under the trade name of bakelite-micarta, is a dark, hard, homogeneous material considerably stronger than hard fibre. It can be worked with sharp tools, punched only in thin sheets, and cannot be molded. It will withstand continuously a temperature of 150 deg. cent. and for short periods 260 deg. cent. It is infusible. The density is about 1.25. Moore gives the following properties of bakelite-micarta, measured at 180 cycles (see Moore, R. W. E., "Properties and Uses of Bakelite-micarta," *Electric Journal*, 1913, pp. 645 to 650): resistivity, $2.13 \times 10^{13}$ ohm-cm.; dielectric constant, 5.2; power-factor, 0.024; dielectric strength, 500 to 1,000 volts per mil; tensile strength, about 20,000 lb. per sq. in.; coefficient of expansion, 0.00002 per deg. cent. It is said to be insoluble in alcohol, benzine, turpentine, weak acids and alkalies, hot water and oils and non-hygroscopic.

**287. Asbestos paper**, comprised of an asbestos base, is a soft, flexible material of little strength and is hygroscopic. It will withstand an operating temperature of 260 deg. cent. without injury. The dielectric strength is on the order of 100 volts per mil.

**Treated asbestos paper.** A variety of treated asbestos paper known as Delta sheeting is impregnated with a black insulating compound which softens at about 120 deg. cent. and melts at about 200 deg. cent. It is claimed that from 2,500 to 5,000 volts is required to puncture it, in thicknesses of 10 to 25 mils.

**288. Pressboard and fuller board.** Pressboard is manufactured from cotton rags and paper clippings, in a number of grades. It is similar to paper, but thicker and less flexible. In the untreated condition it is hygroscopic, and its properties improve with its dryness. Uppenborn gave the resistivity as $11 \times 10^9$ ohm-cm. and Turner and Hobart gave the dielectric strength as 200 to 330 volts per mil. Presspalm is another name for pressboard, applied to a grade manufactured in Germany. The qualities of pressboard are greatly improved by impregnation.

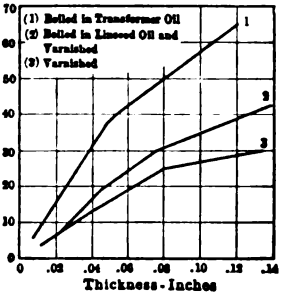

FIG. 35.—Dielectric strength of treated pressboard.

**289. Treated pressboard.** Extensive tests of oiled and varnished pressboard are given by Hendricks in "High-tension Testing of Insulating Materials," *Trans.* A. I. E. E., 1911, Vol. XXX, p. 167. The dielectric constant of pressboard dried and boiled in transformer oil ranges from 4.3 at 13 deg. cent. to 7.5 at 100 deg. cent. The dielectric constant of varnished

Digitized by Google

pressboard is about 2.9 at 20 to 25 deg. cent., measured on 0.1-in. board. The dielectric strength of treated pressboard is given in Fig. 35: curve (1) for pressboard dried and boiled in transformer oil; curve (2) for pressboard dried, boiled in linseed oil and given two coats of varnish; curve (3), dried and given two to four coats of linseed oil and gum varnish, depending on thickness. When these sheets are laid together in laminations, the puncture voltage per mil of complete thickness decreases, but in the case of very thin laminations the puncture voltage does not appear to decrease in as rapid ratio as with single thicknesses.

**290. Vulcanized fibre*** is a hard, dense material of which the principal ingredient is paper or cellulose made from cotton rag stock; the other ingredients are zinc chloride and coloring matter, the latter consisting of analine colors or mineral pigments. The finished material is heavily compressed into slabs, sheets, tubes, etc. The water and chemicals are not completely removed during manufacture and the product is hygroscopic and not a superior insulating material except for moderate voltages. It will absorb about 50 per cent. of its weight of water in 24 hours. The density ranges from 1.0 to 1.5 according to the grade; average 1.4. The resistivity is comparatively low for dielectrics, or on the order of $10^7$ to $10^{10}$ ohm-cm. Certain varieties are said to have a resistivity as high as $7 \times 10^{12}$ ohm-cm., probably in a very dry state. The measurements of dielectric strength by different observers are widely discrepant. Parshall and Hobart gave 10,000 volts as the dielectric strength of all thicknesses from $\frac{1}{4}$ to 1 in. Hendricks gave about 200 volts per mil at thicknesses of 50 to 150 mils, 160 volts per mil at 0.4 in., 100 volts per mil at 0.7 in. and 90 volts per mil at 1.0 in. Others have found values ranging as high as 300 volts per mil; the results depend largely on the dryness of the material. The tensile strength ranges from 10,000 to 20,000 lb. per sq. in. and the compressive strength is from 35,000 to 60,000 lb. per sq. in. Fibre is not soluble in water or oil, but is attacked by strong acids, and swells when soaked in water; upon drying it shrinks appreciably and warps badly. Numerous grades of fibre are manufactured and known by various trade names, as horn fibre, hard fibre, indurated fibre, leatheroid, fish paper, etc. The flexible and more fibrous varieties have better insulating qualities. Impregnation improves the qualities in marked degree.

**291. Treated fibre.** The insulating properties of hard or vulcanised fibre are much improved by treating the pulp with bakelite. A material of this character, known as bakelite-dielecto, is manufactured by The Continental Fibre Co. and is said to have the following characteristics. It is a hard, tough material, light brown or black in color, and manufactured in sheets, tubes and certain special forms; cannot be molded, but can be machined either with or against the grain; is non-hygroscopic and impervious to hot water, oils and ordinary solvents; will withstand continuously a temperature of 150 deg. cent.; resistivity, $1.1 \times 10^{12}$ ohm-cm. at ordinary temperatures, increasing with temperature up to 100 deg. cent.; dielectric strength, 700 to 1,150 volts per mil; average tensile strength, 18,000 lb. per sq. in.; compressive strength, 21,000 lb. per sq. in.

**292. Impregnated fibre duct** is in extensive use for both inside and outside construction. It is made in the form of a cylindrical tube by wrapping many layers of paper or pulp on a mandrel and impregnating it during the process with bitumen or a compound of liquid asphalt and coal tar. It is sometimes known as **bitumenized fibre.** Tests made on a certain grade of this material show that it absorbed from 2 to 3 per cent. of water after 96 hr. immersion; one manufacturer guarantees not more than 0.75 per cent. when the ends are sealed. The compound softens slightly at 55 deg. cent. and commences to break down at about 95 deg. cent. Manufacturer's guarantees on minimum puncture voltage, dry, through a 0.375-in. wall, range from 25 to 50 kv; after prolonged immersion the dielectric strength will usually be lowered, depending naturally upon the amount of moisture absorbed.

**293. Varnished cloth** is a thin white fabric of cotton or linen muslin coated with a mixture of boiled linseed oil, resin and benzine. Upon drying the oil oxidizes in contact with the air and leaves a smooth, hard surface.

---

*See "Manufacture of Hard Fibre," *Electrical World*, Vol. LIII, p. 1437; also see Vol. LV, p. 1342.

Digitized by Google

Successive coats may be added to secure the desired thickness. This material is also known as varnished cambric and as varnished muslin. For varnished cambric the usual value of the constant $k$ in the formula $R = k \log_e (D/d)$ is from 500 to 2,000; $R$ is the insulation resistance of the insulated wire in megohm-miles, $d$ is the diameter of the conductor and $D$ is the outside diameter of the insulation. Dielectric constant, 3.5 to 5.5. Dielectric strength, in commercial thicknesses of 5 to 16 mils, about 500 to 1,300 volts per mil; the Mica Mfg. Co. gives 1,000 volts per mil. Also see tests by Farmer, F. M., "The Dielectric Strength of Thin Insulating Materials;" *Trans.* A. I. E. E., 1913, Vol. XXXII, pp. 2097 to 2131.

Varnished cambric is more elastic than paper and is very suitable for cable insulation. A separator of treated paper, cloth or rubber is applied to the copper core to prevent any action of the varnished cambric film on the copper. Then strips of varnished cambric are taped over the separator with applications of a plastic non-hardening compound between layers to exclude moisture and make the cable flexible. The core is finished by cotton braiding and weather-proofing, or asbestos braiding and flame-proofing, or a lead sheath over tape. In some types of cable the insulation is graded, first using rubber and then varnished cambric. The General Electric Co. recommends a working temperature limit of 80 deg. cent. (176 deg. fahr.) for varnished cambric cables.

**294. Oiled cloth** is a thin, white fabric of cotton or linen muslin coated with two or more applications of pure oxidised linseed oil. The insulating properties are derived chiefly from the oil or compound with which the fabric is impregnated. This material is known by a number of trade names, among them **Empire cloth.** Gray gives the normal dielectric strength, with a 10-mil thickness, as 750 volts per mil; the Mica Insulator Co. gives 1,000 to 1,100 volts before baking and 1,100 to 1,200 volts after baking. Silk, linen, canvas and duck are treated by the same process, with dielectric strengths ranging from 1,100 to 1,450 volts per mil with silk, 1,250 to 1,375 volts per mil with linen and 600 to 775 volts per mil with canvas (Mica Insulator Co.).

**295. Impregnated cloth** is similar to varnished or oiled cloth, with the difference that the fabric is treated with an impregnating compound. One manufacturer employs a mixture of oxidised oil and asphalt; others use an asphaltum or a paraffin base, dissolved in a thinning material. The Mica Insulator Co. gives puncture voltages for "Kabak" cloth (impregnated cambric) ranging from 1,065 to 1,650 volts per mil.

**296. Composite insulation of fibrous materials and mica.** In applying mica to coils or heavy strap conductors it is necessary to use some fibrous material like paper or cotton as a base for the mica. It is customary to build up mica on thin sheets of fish paper or Japanese paper, and to wrap the resultant sheet around the straight parts of armature coils or heavy conductors. It is also customary to build up mica on a thin cotton tape and to use the resultant material for taping coils or heavy conductors. If the amount of paper or tape is small and if the material is applied in such a location, as in an armature slot, that the mica will remain intact even after the paper or the cotton tape has deteriorated, these materials may be expected to withstand fairly high temperatures.

**297. Paper and mica,** or mica paper, is prepared from various grades of paper by coating them with thin mica scales which are made to adhere by means of a cementing varnish such as shellac. The layers of mica and paper are built up in a variety of ways, depending upon the degree of flexibility, or stiffness, desired. Parshall and Hobart give puncture voltages for composite laminæ of alternate paper and mica, ranging from 700 to 1,300 volts per mil, in thicknesses of 5 to 11 mils. Various combinations of paper and mica are manufactured, including Japanese, fish and rope papers and pressboard.

**298. Cloth and mica,** or mica cloth, is prepared from various fabrics by coating them with a thin layer of mica, cemented together with a cementing varnish like shellac. A layer of paper is sometimes added to the combination. An extra flexible cloth is made by using rubber tissue as a binder, instead of cementing varnish.

**299. Cotton insulation for magnet wires,** employed more extensively than any other material except enamel, is applied in one, two or three thicknesses. Untreated cotton is hygroscopic and breaks down at a temperature of 120 deg. cent. The thickness of covering varies with the size of wire (see

Digitized by Google

tables in Sec. 5). Gray gives the puncture voltage of a 7-mil thickness (composed of two layers) as about 150 volts; impregnated, about 600 volts.

**300. Silk insulation for magnet wires** is applied in one or two thicknesses, ranging from 1 to 2.5 mils per layer. While it is somewhat hygroscopic in the untreated condition, it has superior insulating properties compared with cotton, and is much improved by impregnation. Neither cotton nor silk are the equal of baked enamel (Par. **351**) in dielectric strength.

**301. Asbestos insulation for magnet wires.** Asbestos insulation can be applied to wires and small straps with the use of binding materials, but in all cases, except in that of asbestos tape which can readily be used in taping armature or field coils, the mechanical qualities are quite poor. Asbestos windings also require considerable space if used in sufficient thickness, they are not in themselves moisture-proof, they have low dielectric strength, and do not give a smooth surface.

Deltabeston magnet wire is insulated with asbestos fibre cemented to the wire with a special bond. It is claimed that the maximum continuous working temperature is 150 deg. cent.; for short periods, 260 deg. cent. The insulation thickness is about the same as double cotton and breaks down at 300 to 600 volts.

**302. Tapes.** Insulating tapes are chiefly of four varieties: (a) those woven from cotton or silk and untreated; (b) those woven from cotton and treated with insulating varnish, or cut from treated cloth; (c) those cut from cloth which has been loaded with rubber or adhesive compound. The lay of the threads is arranged in three different ways, straight, biased and webbed; the last one is the strongest and does not stretch readily. (d) Paper tapes, treated and untreated, are cut from finished stock. See "Specifications and Tests for Insulating Tapes," *Electrical World*, Vol. LVII, p. 488; also Vol. LVI, p. 689.

**303. Untreated tapes** are hygroscopic and for that reason are not entirely satisfactory unless finally impregnated or protected from moisture. Gray states that a half-lapped layer of untreated cotton tape 6 mils thick will withstand about 250 volts when dry; about 1,000 volts when impregnated. Precautions should be taken to detect the presence of bleaching and chemical matter, such as chlorine, which may attack copper. Webbing is sometimes used for mechanical protection, aside from its insulating qualities.

**304. Varnish-treated tapes** are cut from sheets of treated cloth, such as Empire cloth, varnished cambric and the like, and are used for taping windings which cannot readily be impregnated. They are cut straight or on the bias, the latter being sometimes preferred for taping uneven surfaces. See treated cloth, Par. **293** to **295.**

**305. Rubber-treated tapes** are composed of fabric loaded with plastic rubber gum or compound in a soft adhesive state. Such tapes are used extensively in making water-proof joints on underground rubber-insulated cables, or in other locations where a moisture-repellent wrapping is desired. They are frequently used in conjunction with a splicing gum of similar composition, and protected by water-proof insulating compounds and outside wrappings of adhesive tape with insulating paint over all. In the case of underground cables a lead sleeve is wiped over the whole joint, making it completely water-tight.

**306. Adhesive or friction tape** is composed of fabric loaded with a sticky or adhesive compound. The base of the compound in the more expensive grades is rubber gum, adulterated with fillers in various well-known ways, while the less expensive grades contain little or no rubber and its place is taken by one of the numerous bituminous compounds. This kind of tape possesses fair insulating properties and is very extensively used in low-tension work.

**307. Paper tapes** of both the treated and the untreated varieties have a most extensive use in the manufacture of paper-insulated cables for power and communication service. See paper, Par. **284.**

**308. Asbestos tape,** or a tape having a base of asbestos fibre, is superior in its heat-resisting properties to cellulose materials such as paper and cloth. Such tapes are usually known by trade names, among them being deltatape. The latter it is claimed can be raised to 260 deg. cent. before breakdown occurs; puncture voltage, about 250 volts per mil.

## MOLDED COMPOSITIONS

**309. Molded insulation** embraces a great number of different compositions and compounds, which are difficult of classification. The chief ingredients of some of these materials are well known, while others are made by secret formulas and processes. Among the raw materials employed in the manufacture of molded materials are mica, asbestos, silica, clay, alkaline earths, wood pulp, cotton, hemp, flax, asphalt, camphor, hydraulic cement, rubber, shellac, copal, dammar gum, rosin, paraffin wax, linseed oil, turpentine, benzine, alcohol, phenol and formaldehyde. The following general classification of molded materials has been adapted from "Classification and Characterisation of Molded Insulations," by E. Hemming (*Electrical World*, 1914, Vol. LXIII, pp. 761 to 762, 798 to 799, 813 to 817). The resisting properties given for each class of material below should be considered in connection with more specific particulars in the paragraphs immediately following.

| Class | Allowable temperature (deg. cent.) | | Megohms per in-cube* | Dielectric strength (volts per mil)† | Tensile strength (lb. per sq. in.) |
|---|---|---|---|---|---|
| | Continuous | Momentary | | | |
| Organic, hot-molded | 80 | ..... | 513 | 143 to 361 | 940 to 2,000 |
| Organic, cold-molded | 300 | 500 | 380 | 84 to 167 | 920 to 1,550 |
| Inorganic, cold-molded | 900 | 1,500 | 900 | 70 to 72 | 1,985 to 2,920 |
| Rubber compounds | 80 | 100 | ..... | ..... | ..... |
| Organic plastics | 80 | ..... | ..... | ..... | ..... |
| Synthetic resinous products | 150 to 250 | 300 | 40 | 42 to 333 | 2,880 to 4,750 |
| Molded mica | 80 | 175 | ..... | ..... | ..... |

* Minimum observed value after 72 hr. immersion in water.
† Tests made between blunt needle points; thicknesses of test pieces, ⅛ to ¼ in.; tested dry.

**310. Aetna material** is a hard composition employed chiefly for strain insulators. Tests made by Symons (*Jour.* I. E. E., 1904) on a strain insulator of this material gave the following results: Resistance, 20,000 megohms; puncture, 11,000 volts; tensile strength, 5,500 lb.; absorption of water, 3.2 per cent. of its own weight after 1.5 hr. immersion at 49 deg. cent. Other tests made on this material gave a dielectric strength of about 90 volts per mil; tensile strength, 1,400 lb. per sq. in. It will withstand great heat, but tends to become brittle at high temperatures.

**311. Ambroin** (made in Berlin) is a heat-resisting molded material manufactured in numerous grades, some of which are claimed to be fireproof, while others are suitable for temperature limits of 100 deg. cent. and some as 82 deg. cent. The manufacturers claim that it is moisture-proof, does not shrink, and can be worked and machined. The density ranges from 1.4 to 1.8, according to quality. Tests made at the Reichanstalt on grade "F" gave a dielectric strength of 800 volts per mil, in a thickness of 13 mils. The tensile strength is about 2,100 lb. per sq. in. and the compressive strength about 2,700 lb. per sq. in.

**312. Asbestos-mica** comprised of asbestos and mica bound together with shellac, is manufactured by the Johns-Manville Co. under the trade name of "molded mica." In appearance it has a dark color and a smooth hard finish. It can be molded into any shape, either with or without metal parts. It softens at about 65. deg cent. and has a safe working temperature of 55 to 60 deg. cent. The manufacturer gives the dielectric strength as about 335 volts per mil in a thickness of 0.25 in.; tensile strength, 8,500 lb. per sq. in.; but slightly affected by moisture; attacked in some degree by acids, depending upon their character and concentration. See *Electrical World*, 1912, Vol. LX, pp. 893 and 894.

Digitized by Google

**313. Asbestos molded with a binder,** known under the trade names c gummon, hemit and tegit, is manufactured by the Hemming Mfg. Co from whom the following data was obtained. Gummon is black and can b highly polished; tegit is dark brown and can be polished, though less highl than gummon; hemit is made in both gray and black and will also take polish. The density varies, in the neighborhood of 2. These material are suitable only for molding; are infusible, but will gradually carbonize a higher than working temperatures; will not resist concentrated acid; are nc recommended for working pressures above 1,000 volts.

| | Ohm-cm. at 22 deg. cent. (Bur. of Stds.) | Max. working temp. (deg. cent.) | Dielectric strength (volts per mil) | Strength (lb. per sq. in.) | | Absorption of moisture (per cent.) |

Also see Hemming, E. "Molded Electrical Insulation and Plastics;" Clausen and Co., New York, 1914.

**314. Asbestos wood or lumber,** known also by the trade names "Trans ite Asbestos Wood" and "Asbestos Building Lumber," consists of asbesto fibre and hydraulic cement, and is used as a substitute for wood in buildin construction. It is also used to some extent as a substitute for slate an marble in electrical construction. The following data (Par. **315** and **316** was furnished by C. L. Norton; also see his paper entitled, "Some Refractory Substitutes for Wood," *Jour.* A. S. M. E., 1912; and "The Manufactur and Use of Asbestos Wood," on pp. 375 and 379 of "Technology and Industrial Efficiency," McGraw-Hill Book Co., Inc., New York, 1911.

**315. Transite asbestos wood** is light gray in color and is manufactured in sheets up to about 4 ft. by 8 ft. by 2 in. It has a density of about 2.0 It can be sawed and bored like wood but is harder and slower to cut. At 600 deg. cent., partial dehydration and partial loss of strength occurs, but it does not soften. At 1,100 deg. cent. the material holds shape and considerable portion of its strength, but it will not stand temperatures above 1,400 deg. cent. The temperature coefficient of expansion at ordinary temperatures is about 0.000008 per deg. cent. The thermal conductivity is 0.0005 cal. per cm-cube per sec. per deg. cent. Transverse breaking tests give a modulus of rupture of about 5,000 lb. per sq. in., and the crushing strength is from 20,000 to 25,000 lb. per sq. in. When dry, at or near 20 deg. cent., it has a resistivity of about 150,000 megohm-cm. It is dissolved slowly by acids. When used in dry or hot places it is suitable for electrical insulation and is tougher than slate or marble. Since it absorbs moisture it is not suitable for damp locations.

**316. Ebony asbestos wood** is asbestos bonded with magnesia, cement and saturated with an insulating compound. It is black, smooth and glossy and has a density of about 1.9. It can be worked the same as slate, but more rapidly and easily. The working temperature limit is about 200 deg. cent.; it does not soften; the melting-point is above 1,400 deg. cent. The coefficient of expansion is 0.000010 per deg. cent. The thermal conductivity is 0.00065 cal. per cm-cube per sec. per deg. cent. It has a modulus of rupture of about 5,000 lb. per sq. in. and a crushing strength of 15,000 lb. per sq. in. At 20 deg. cent. after 96 hr. immersion the resistivity is above $3\times10^6$ megohm-cm. and changes 5.3 per cent. per deg. cent. The disruptive strength is greater than that of slate or marble, and it also withstands better the effects of surface arcing. It is also tougher than slate or marble.

**317. Bakelite and bakelite compositions.** Bakelite is a condensation product of phenol, manufactured in three grades. Bakelite "A" is the initial raw material and exists in liquid, pasty or solid condition; upon heating it is converted into "B" which is an intermediate solid product,

Digitized by Google

softening under application of heat and suitable for molding; bakelite "C" is the final product, produced by heating "A" or "B," and is a hard, non-resinous, infusible solid, in appearance resembling amber or hard rubber. In color it can be made transparent or opaque; colorless to yellow, brown, red and black. The coloring matter, when any is used, consists of organic dyes or mineral pigments. The raw material is sold in dissolved, liquid or solid condition, and is used for varnish, lacquer, enamel, impregnation, adhesive cement, plastic molding compositions and molded articles. It can be molded into any shape by casting or by forming in the hot press, and will receive metal inserts. In condition of final hardness it can be worked, machined and polished like amber or hard rubber, and can be used at continuous temperatures considerably above 100 deg. cent. It is not a good conductor of heat. For short periods it will stand 250 to 300 deg. cent. Swoboda gives 230 deg. cent. as the maximum working temperature of bakelite-asbestos. At higher temperatures it is infusible, but chars. It is not attacked by the solvents or many of the acids, but will not withstand hot sulphuric acid, nitric acid, bromine or strong alkaline solutions; the effect of chemicals is dependent in some degree upon the grade of material. It is non-hygroscopic, and is said to resist steam and boiling water. The data given below were furnished by Dr. L. H. Baekeland, the inventor of bakelite.

| | Density | Dielectric strength (volts per mil) | Strength, (lb. per sq. in.) | | Coef. of expansion per deg. cent. |
|---|---|---|---|---|---|
| | | | Tensile | Compressive | |
| Bakelite "C" | 1.26 | 560 | 5,000 | 26,000 | 0.00011 |
| Baked film of bakelite varnish No. 2 | ..... | 2,500 | ..... | ..... | ..... |
| Bakelite-wood fibre | 1.34 | 530 | 4,200 | 27,000 | 0.000034 |
| Bakelite-asbestos | 1.90 | 200 | 4,200 | 24,000 | 0.000023 |
| Bakelite-micarta (sheet) | ..... | 950 to 1,120 | 16,500 | ..... | ..... |
| Bakelite-dielecto (sheet) | ..... | 635 to 1,130 | ..... | ..... | ..... |

Resistivity of "C" at 26 deg. cent., $5\times10^{11}$ to $3\times10^{12}$ ohm-cm.; dielectric constant, 4.1 to 8.8. The resistivity and the dielectric strength decrease at temperatures above 75 deg. cent. For further data on bakelite see: *Journal of Ind. and Eng. Chem.*, 1909, Vol. I, No. 3 and No. 8; 1911, Vol. III, No. 7 and No. 12; 1912, Vol. IV, No. 10; 1913, Vol. V, No. 6. *Trans.* A. E. S., 1909, Vol. XV. *Elec. World*, 1911, Vol. LVII, pp. 632 to 634. *Met. and Chem. Eng.*, Jan. 1912. *Jour. Soc. Chem. Industry*, June 16, 1913, Vol. XXXII.

**318. Celluloid,** formerly known as xylonite, is composed essentially of soluble guncotton (pyrolin) and oil (camphor). In texture and color it resembles ivory, and is variously colored in imitation of amber, coral, tortoise shell, etc. It is very slightly hygroscopic and can be molded into any form by softening in boiling water. It is highly inflammable. The density is 1.44. The resistivity at ordinary temperatures is from $2\times10^{10}$ to $8\times10^{10}$ ohm-cm. According to Thomas (*Jour. Franklin Institute*, 1913, Vol. CLXXVI, pp. 283 to 301), celluloid tested at 1,000 cycles has an effective resistivity of $2\times10^{9}$ ohm-cm. and a dielectric constant of 13.3. Clear celluloid has a dielectric strength of 250 to 700 volts per mil at 20 deg. cent., and 100 to 300 volts per mil at 100 deg. cent.; colored samples, 250 to 470 volts per mil (Turner and Hobart). Thomas gives a puncture voltage of 1880 volts per mil, at 1,000 cycles. At 920 cycles the effective resistance is $28\times10^{9}$ ohm-cm.; dielectric constant, 4.02; power-factor, 0.012 (Fleming and Dyke).

**319. Condensite** is a molding material of which the chief constituent is a compound resulting from chemical reaction between phenol and formaldehyde, classed as a phenolic condensation product. It can be prepared in many forms, transparent or translucent, in a variety of colors; it is adaptable as molding material, varnish, enamel, impregnating material and cement. The first step in its manufacture is the production of a resinous gum-like

Digitized by Google

substance which will not harden under heat; this product is heated and then combined with a hardening agent, producing a hard, infusible and practically insoluble substance which the manufacturer (Condensite Co. of America) claims is high in dielectric and mechanical strength and heat resistance. The following data on the properties of molded condensite were furnished by the manufacturer: Density, 1.25 to 2.0; not hygroscopic, unaffected by water, insoluble in the ordinary solvents and oils, attacked by strong nitric acid and caustic potash, slightly attacked by sulphuric acid. The resistivity at 22 deg cent. is about $4 \times 10^{16}$ ohm-cm. (Bur. of Stds.); dielectric strength, about 300 to 400 volts per mil at a thickness of 0.15 in. and 500 to 600 volts per mil at a thickness of 0.04 in.; tensile strength, 4,300 lb. per sq. in.; compressive strength, 26,000 lb. per sq. in.; not perceptibly affected by 48 hr. of exposure to a temperature of 200 deg. cent.; maximum working temperature, 300 deg. cent. (Swoboda, *Elec. Jour.*, May, 1913). Also see *Electrical Review and West Elec.*, Vol. LX, p. 199.

**320. Dielectrite** is a black molded composition composed of vegetable fibre and mineral filler. It is molded and vulcanised by the application of heat. Resistivity at 22 deg. cent., $5 \times 10^{12}$ ohm-cm.

**321. Electrose** is a dark brown or black composition of hard, tough quality which it is claimed is non-hygroscopic and not affected by water or oil. It can be molded in any form, will hold metal inserts, and can be given a smooth glossy finish. The working temperature limit is about 95 deg. cent. Resistivity at 22 deg. cent., $1 \times 10^{14}$ to $200 \times 10^{14}$ ohm-cm. The manufacturer (Electrose Mfg. Co.) claims a dielectric strength of at least 600 volts per mil, in a thickness of $\frac{1}{8}$ in. Electrose is used in the manufacture of many different forms of insulators and bushings and is also made in pliable insulating flooring. See *Electrical World*, Vol. LIV, p. 797 and Vol. LVI, p. 887.

**322. Gohmak** is a molded substitute for hard rubber made by the Vulcanised Products Co. The density ranges from 1.4 to 1.8 according to composition. The claim is made that it is non-hygroscopic and insoluble in oils and weak solutions. Resistivity, on the order of $2 \times 10^{16}$ ohm-cm. at ordinary temperatures, decreasing with rising temperature. Dielectric strength, on the order of 400 volts per mil, at a thickness of 0.25 in. Tensile strength, 9,000 to 12,000 lb. per sq. in. Softens slightly at 100 deg. cent.

**323. Insulate** is a black molded composition composed of mineral compound and resembles hard rubber. It can be moulded in any shape and can be worked and machined. The manufacturers (General Insulate Co.) claim that it is non-hygroscopic, insoluble in all weak solutions and has a maximum working temperature of 150 deg. fahr. The resistivity of No. 2 grade at 22 deg. cent. is $8 \times 10^{15}$ ohm-cm. The dielectric strength is on the order of 45 volts per mil, at a thickness of 0.4 in.

**324. Molded mica** is made of finely split mica scales held together by a strong insulating varnish, binder, or cement, such as shellac, the sheets or forms thus built up being subjected to heat and pressure. These compositions are more or less heat resisting, dependent upon the nature and proportions of the binder employed. They are known by a variety of trade names such as micanite, mica plate, micabond, micabeston, turbomic, formica, megomit, megotalc, etc. The less binding material they contain, the nearer they approach the properties of natural mica. Such reconstructed or molded mica is made in three commercial forms, as follows: (1) Molded plate, which becomes flexible when heated and in that condition can readily be formed into various shapes such as rings, troughs, spools, and, in thinner sheets, rolled into tubes. Upon cooling it regains its rigidity. It can be used for any purpose where very high temperatures are not encountered, except for commutator bars. (2) For insulating commutator segments. It cannot be molded and offers great resistance to heat. Canadian amber mica is preferred for this purpose. (3) Flexible sheets which may be bent to shape without application of heat, for insulating armature slots, magnet and commutator cores, etc. It is also used in conjunction with tapes for insulating wires and cables.

Rayner concluded from his tests (National Physical Laboratory) that generally speaking, thin qualities of micanite up to about 1 mm. will withstand a stress of 20,000 volts per mm. (500 volts per mil) in air for 10 min. Above this thickness, up to 2.5 mm., there is more difficulty in making material which will withstand this stress, and usually the material withstands the voltage longer under oil.

Digitized by Google

The Mica Insulator Co. gives the following dielectric strengths for micanite of different grades:

| Use | Grade | Thickness (mils) | Volts per mil |
|---|---|---|---|
| For molding | India | 10. to 125. | 955 |
| For commutators | India | 10. to 125. | 955 |
| For molding | Amber | 20. to 62.5 | 830 |
| Plate for flat work | India | 62.5 to 500. | 800 |
| Flexible | India | 5. to 125. | 588 |

The resistivity is on the order of $10^{15}$ ohm-cm.

**325. Bonite** is a black moulded composition, the properties of which are given as follows by the Northern Industrial Chemical Co. Density, 1.8; can be molded into any shape and will receive metal inserts; will take a high polish; infusible and insoluble; will not support combustion; absorbs 0.5 to 1 per cent. of water after 24 hr. immersion; dielectric strength, 80 volts per mil.

**326. Sternoid** (Dickinson Mfg. Co.) is a black, heat-resisting, molded material which the manufacturers claim has high dielectric and tensile strength and is heat-proof up to 260 deg. cent. The same manufacturers also produce other molded materials known as **stern-asbeston**, heat-proof up to 200 deg. cent.; **stern-condensite**, heat-proof up to 175 deg. cent. and capable of being worked, machined and polished; rubber-substitutes, heat-proof up to 70 deg. cent.

**327. Vulcabeston** (Johns-Manville Co.) is an insulating material made of **asbestos and rubber**, the latter being used as a binder. This material is grayish brown in appearance, can be molded into nearly any shape, and has a surface which will not take a smooth finish. The softening point is about 175 deg. cent., with a safe working temperature of about 150 deg. cent. The resistivity at 22 deg. cent. is about $2 \times 10^{10}$ ohm-cm. The dielectric strength is about 90 volts per mil, the test pieces being 0.25 in. thick. Change in temperature has no effect on the dielectric strength. Since this material is of a fibrous nature, it is not suitable for use in damp places. Acids have a slight effect upon it. The transverse strength is 3,000 lb. per sq. in. See *Electrical World*, 1912, Vol. LX, pp. 893 and 894.

**328. Vulcabeston No. 201** (Johns-Manville Co.) is a material composed of **asbestos and a special gum** used as a binder. In appearance it has a brown mottled surface which will take a very high finish. Intricate and complicated pieces can be readily molded from it, using metal inserts if desired. The softening temperature is between 260 and 300 deg. cent., and the safe working temperature is about 230 deg. cent. The dielectric strength is about 115 volts per mil with test pieces 0.25 in. thick. Transverse strength, 9,000 lb. per sq. in. Not affected by most acids, and not affected by oil or water.

**329. Vulcalose** is a molded material having the properties of hard rubber, except that it is said to be considerably tougher. It can be molded in any form and is used, among other purposes, for insulators.

## RUBBER AND ITS DERIVATIVES

**330. Rubber or caoutchouc** is the general name applied to a great number of different natural gums, the different varieties being of decidedly unlike characteristics, but having among themselves certain common properties and similar constituents. The synthesis of rubber shows that it belongs with the terpenes, having the formula $(C_{10}H_{16})_n$, but thus far all attempts to show the size of the molecule have been unsuccessful. In addition some of the crude rubbers contain proteids, resins, hydrocarbons, etc.; in some cases it requires extensive treatment to obtain the pure gum. Crude rubber is obtained by coagulating and drying the milky latex obtained from certain species of trees and plants, the principal sources being in South America, Central America, Africa and Asia, the Amazon district of South America being especially noted for its high-grade rubber. Crude rubber is affected in marked degree by temperature, being soft and sticky when warm but stiff when cold.

Digitized by Google

**331. Reduction of crude rubber.** The lumps or biscuits of crude rubber are boiled in water, ground, washed, dried, mixed with sulphur, adulterants and filler and then calendered. For details of the process see Perrine, F. A. C. "Conductors for Electrical Distribution," New York, 1903; and Esch, W. "Handbook for India-rubber Engineers," Hamburg, 1912. Owing to the high cost of pure rubber it is almost universally adulterated and many rubber products do not contain over 20 to 30 per cent. of pure gum, and sometimes much less. Among the numerous adulterants in use are rubber substitutes, ozokerite, paraffin, pitch, oil, etc., and fillers such as zinc oxide, white lead, red lead, barium sulphate, magnesium carbonate, barium carbonate, chalk, lamp-black, talc, alumin flakes, etc.

**Vulcanization.** When rubber and sulphur are heated to a temperature above the melting-point of the latter, 120 deg. cent., the two combine and form a new product termed vulcanized rubber, which is stronger, more elastic and less susceptible to temperature changes than pure rubber. The degree of vulcanization depends upon the proportion of sulphur, the temperature and the duration of heating.

**332. Rubber substitutes** in the true sense have not yet been produced on a commercial scale. There are certain so-called substitutes, produced from vegetable oils by processes of vulcanization or oxidation, which can advantageously be mixed with rubber for the production of certain articles. Rubber substitutes used not infrequently in wire insulation consist principally of oxidized oils, paraffin, resins and rubber shoddy. The latter is a compound obtained by treating old rubber with steam, sulphuric acid and chloride of zinc, thus removing most of the vegetable fibres and the sulphur, but leaving the mechanical admixtures of earth and oxides employed in the original manufacturing process. Such substitutes are usually known under trade names.

**333. Electrical properties.** The resistivity is on the order of $10^{14}$ to $10^{16}$ ohm-cm., varying greatly according to the composition and increasing with the content of pure rubber. The temperature coefficient is negative and unusually large, ranging from 2 to 4 per cent. per deg. cent. Del Mar states that at any given temperature the rate of change of resistance per deg. of temperature change is approximately proportional to the resistance at that temperature, values of the factor ranging from 0.02 to 0.03 for 30 per cent. Para compound. Values of $k$ in the formula $R = k \log_{10}(D/d)$ for insulation resistance of cylindrical wires in megohm-miles, are variable between wide limits, ranging from about 1,000 to 20,000; $d$ is the diameter of the wire and $D$ is the outer diameter of the insulation, in the same units. The value of $k$ is very much higher with alternating currents.

The dielectric constant of pure vulcanized rubber is from 2 to 3; rubber compounds, 3 to 4. Jona gives values as high as 6 for certain compounds containing relatively large percentages of Para.

The dielectric strength of high-grade rubber compound ranges from 300 to 500 volts per mil; it decreases quite appreciably for long periods of electrification. Lufkin states (*Electrical World*, 1913, Vol. LXI, p. 1310) that for each rubber compound there is a critical temperature at which the puncture voltage is a maximum. This ranged between 40 deg. and 80 deg. cent. for five different grades, in a certain series of tests. One particular grade, or high quality, gave a maximum at 70 deg. cent., being 30 per cent. above the value at 20 deg. The range was carried to 100 deg. cent. at the upper limit, and 0 deg. at the lower.

Fleming and Dyke measured the power-factor of rubber at 920 cycles and found values of 0.005 for pure India-rubber and 0.002 for vulcanised India-rubber. For further data on electrical properties, consult the following:

**334. Mechanical properties.*** The density of pure rubber is 0.93 to 0.97; rubber compounds, 1.7 to 2.0. A properly vulcanised compound of high-grade rubber suitable for the best hose and packing, has a tensile strength of about 2,000 lb. per sq. in. and may be stretched to about seven times its original length. The physical properties, however, are subject to wide variations depending upon the relative proportions of gum and filler and the extent of vulcanization. The real value of rubber depends upon the length of time which it will retain its desirable properties. It often deteriorates less rapidly when in use than when lying idle; deterioration is accelerated by heat and especially by sunlight, probably as the result of oxidation. Other things being equal, the better grades are stronger, more elastic and more durable than the poorer grades.

The following tests made by the Bureau of Standards indicate the properties of six different grades of rubber (See Circular No. 38).

| Sample | Tensile strength (lb. per sq. in.) | | Ultimate elongation (per cent.) | | Set† (per cent.) | |
|---|---|---|---|---|---|---|
| | Longitudinal | Transverse | Longitudinal | Transverse | Longitudinal | Transverse |
| 1 | 2,730 | 2,575 | 630 | 640 | 11.2 | 7.3 |
| 2 | 2,070 | 2,030 | 640 | 670 | 6.0 | 5.0 |
| 3 | 1,200 | 1,260 | 480 | 555 | 22.1 | 16.3 |
| 4 | 1,850 | 1,700 | 410 | 460 | 34.0 | 24.0 |
| 5 | 690 | 510 | 320 | 280 | 27.5 | 25.0 |
| 6 | 880 | 690 | 315 | 315 | 34.3 | 25.9 |

† After 300 per cent. elongation for 1 min., with 1 min. rest. The set and the tensile strength were determined on different test pieces.

**335. The safe working temperature** limit for cables insulated with rubber gum or rubber compounds is 50 deg. cent.

**336. Chemical activity.** Rubber compounds containing sulphur are injurious to copper. Rubber-covered copper wires should be protected by a coating of tin. Rubber is attacked by oil and therefore rubber-covered conductors should never be immersed in insulating oils, which applies to any form of rubber insulation.

**337. Specifications and tests** for 30 per cent. Hevea rubber-insulating compound were prepared in 1914 by a joint rubber insulation committee appointed by a group of manufacturers and users of rubber compounds. The full report and specifications will be found in the *Proc.* A. I. E. E., Jan., 1914, pp. 121 to 140. Specifications for rubber-insulated wire have been prepared by a number of associations; see R. S. A. "Manual."

**338. Chatterton's compound** is composed of 3 parts gutta-percha, 1 part rosin and 1 part Stockholm tar. It is used for filling the interstices between the strands of cable conductors before applying gutta-percha, in submarine cables.

**339. Clark's compound** consists of 60 parts mineral pitch and 40 parts of finely ground sand. It is employed to impregnate jute yarn wrapping on the outside of armored submarine cables.

**340. Gutta-percha** is a natural gum, the best quality of which is obtained from the Isonda gutta-tree found in Sumatra, Borneo and Malacca. A gum known as **Ballata**, which is quite similar to gutta-percha, is found in Venesuela. The density of gutta percha is 0.97 to 0.98 and its properties are generally the same as those of pure rubber. Crude gutta-percha is reduced in the same manner as crude rubber, but unlike the latter it is used in the pure state, principally for submarine cable insulation. Fleming and Dyke found that at 920 cycles the effective resistivity is $34 \times 10^9$ ohm-cm.; apparent dielectric constant, 2.86; power-factor, 0.020. For extended information on gutta-percha and its properties see Clouth, F., "Rubber, Gutta-

percha and Balata," Cologne, 1903; Seeligmann, Torrilhon and Falcounet "India-rubber and Gutta Percha," 1910; Del Mar, W. A., "Electric Power Conductors," 2d edition, New York, 1914; Kempe, H. R., "A Handbook of Electrical Testing," 7th edition, London, 1908.

**341. Hard rubber or ebonite** is a rubber compound containing a large percentage of sulphur and highly vulcanised. It is a hard dense material possessing many desirable properties as an insulator at temperatures not greatly exceeding normal. The resistivity is on the order of $10^{18}$ to $10^{19}$ ohm-cm. at ordinary temperatures; the surface resistivity is impaired by exposure to sunlight (See Scientific Paper No. 234, Bureau of Standards). The dielectric constant is from 1.9 to 3.5. In small thicknesses, of 20 mils the dielectric strength ranges from 1,700 to 3,750 volts per mil, tested between 2-in. spheres; 1,000 to 2,000 volts per mil, tested between flat electrodes. At 920 cycles it has an effective resistivity of about $1.5 \times 10^{11}$ ohm-cm.; dielectric constant, 3.17; power-factor 0.005 (Fleming and Dyke). Mechanically it is brittle, but can be worked, machined and polished; tensile strength, about 1,100 lb. per sq. in. and compressive strength about double; density, 1.2 to 1.25. It is attacked by oils and ozone, but is non-hygroscopic. See Farmer, F. M., "The Dielectric Strength of Thin Insulating Materials," *Trans.* A. I. E. E., 1913, Vol. XXXII, pp. 2097 to 2131; also Paterson, Rayner and Kinnes, "Notes on the Testing of Ebonite for Electrical Purposes," *Jour.* I. E. E., 1913, Part 217, Vol. L.

**342. Kerite** is a vulcanised compound of oxidised linseed oil and rubber combined with various vegetable oils, invented by A. G. Day. According to Perrine* it has a specific insulation resistance somewhat less than pure rubber, but is said to be mechanically more durable than any insulation manufactured from pure rubber. It is employed in the insulation of wires and cables as a substitute for the usual rubber compound. The value of the constant $k$ in the formula $R = k \log_{10} (D/d)$ is given by the Kerite Ins. Wire and Cable Co. as 4,000 at 60 deg. fahr.; $R$ is the insulation resistance of the wire in megohm-miles, $d$ is the diameter of the conductor and $D$ is the outside diameter of the insulation.

**343. Sulphur** has a resistivity of $10^{17}$ ohm-cm. at 22 deg. cent.; dielectric constant, 2.2 to 3.9; power-factor at 920 cycles, 0.0003.

**344. Vulcanite.** See hard rubber, Par. **341.**

## VARNISHES AND COMPOUNDS

**345. Solidifying materials,** such as varnishes, which are applied as liquids and emerge as solids, are of interest chiefly in their final state. They are divisible broadly into two classes: (1) those employed to impregnate or treat basic materials, such as the fibres and the pulps; (2) those employed as filling compounds, to permeate or seal extensive voids which otherwise would offer lodgment for moisture and deleterious foreign matter. The properties of the former class are obviously of importance, principally, in association with the treated or impregnated base; while materials of the latter class constitute a species to themselves.

**346. Insulating varnishes** are divisible, according to their applications, into four groups:† (A) For impregnating windings; (B) for treating papers and fabrics; (C) for cementing purposes; (D) finishing varnishes. They are also divisible, according to their properties, into (a) oxidising and (b) non-oxidising, and again into (1) air-drying and (2) baking. Oxidising varnishes of class A are frequently composed of linseed oil with a resinous base of copal or other fossil gum, and when thoroughly oxidised are almost impervious to oil and moisture. The drying action in linseed-oil varnishes takes place first by the evaporation of the volatile solvent and then by the oxidation of the oil and the gum; the latter action is hastened by the addition of mineral drier, the quantity of which depends upon whether air-drying or baking varnish is desired. In another form of oxidising varnish the gum base is replaced by asphaltum, but this is said to lower the dielectric strength and the resistance to attack by oil. Non-oxidising varnishes of class A contain a

Digitized by Google

base of gum or asphaltum with a spirit solvent, shellac varnish being an example. Varnishes of class B are composed in some instances of linseed oil with a gum base, and a mineral drier such as manganese borate or litharge; in other cases linseed oil alone is used. It is essential that varnishes of class A and class B should be as nearly as possible impervious to moisture, and, for oil-immersed apparatus, not attacked by transformer oil. In the varnishes of class C, shellac is probably the most extensively employed. Class D varnishes are used mainly for the sake of appearance and to provide a hard smooth exterior surface in the interest of cleanliness.

**347. Impregnating, filling and sealing compounds** are prepared from a multitude of different formulas. In most instances their composition is guarded as a manufacturing secret and they are marketed under various trade names, such as Ajax, Armalac, Benolite, Insulatine, Insulac, Ohmlac, Osite, Resistolac, S. V. W., Victolac, Voltalac, etc. Impregnating varnishes have been superseded to some extent by compounds having an asphaltum or paraffin base dissolved in thinning material, which are chemically more inert, more resistant to moisture, better heat conductors and capable of filling the interstices of windings. Their use is chiefly limited by their temperature characteristics. The compounds on the market offer a fairly wide range of choice in temperature characteristics, the softening or flow points varying from about 50 to 130 deg. cent. The Minerallac Elec. Co. gives the following properties for Minerallac No. 2, a semi-solid compound: softening point, 48 deg cent.; melting-point, 63 deg.; flash-point, 202 deg.; burning-point, 218 deg.; resistivity, $1.3 \times 10^{13}$ ohm-cm.; dielectric constant, 2.1; dielectric strength, 1,000 volts per mil.

In the case of filling and sealing compounds, the thermal properties are relatively of more importance than the dielectric strength; chemical inertness and imperviousness to moisture are very important. These compounds should be tested for softening point, evaporation, melting or pouring point, flash-point, burning-point, characteristics at extremes of working temperature, cubical expansion, chemical activity, effect of moisture and electrical properties.

**348. Vacuum drying and impregnation** is very extensively employed in the application of fluid or liquid treating materials. The winding or substance to be impregnated is first dried in a steam-heated, vacuum chamber; then the hot insulating fluid is admitted, the vacuum is let down, and pressure is applied, to the extent sometimes of 50 lb. per sq. in. In this way the moisture is driven out and the maximum degree of impregnation is secured.

**349. Asphalt** is a natural mineral pitch of bitumenous character employed in the manufacture of insulating varnishes and impregnating compounds. Chemically it is a mixture of hydrocarbons, generally black in color, hard at ordinary temperatures, becomes viscous at about 70 deg. cent. and melts at about 100 deg. cent. The density is from 1.04 to 1.40. It is more or less soluble in oil of turpentine, ether, alcohol and chloroform. The dielectric constant is about 2.7 and the dielectric strength according to Symons is 30 volts per mil at a thickness of $\frac{1}{16}$ in.

**350. Bitumen.** The term originally referred only to asphalt or **mineral pitch**, but its meaning is now extended to embrace any of a number of inflammable mineral substances consisting mainly of hydrocarbons, and including also the mineral **tars**. Coal-tar pitch is a fair insulator, but is brittle; according to Symons it has a dielectric strength of about 50 volts per mil.

**351. Enamel (baked) insulation for small magnet wires** has to a great extent displaced cotton and silk, or is used in conjunction with them. The composition of the enamelling compounds used by different manufacturers is guarded with much secrecy; the base of the compound, in some instances, is said to be **stearin pitch**. Chemically stearin is glyceryl tristearate; it melts at 67 deg. cent. It is also known as tristearin and is a prominent constituent of many animal and vegetable fats and oils.

The wires are drawn slowly through a warm bath of the melted compound and then through a baking oven, the process being repeated to secure as many coatings as required. One of the defects sometimes found in the coating is the occurrence of very small holes, like pin holes, exposing the conductor; such defects can be detected by drawing the wire through a mercury bath. The coating is usually very thin, on the order of a few tenths of a mil. The dielectric strength varies over a range of about 300 to 1,200 volts (max.)

Digitized by Google

per mil, an average value being 500 to 600 volts per mil, or about four times the value for silk. The electrical resistivity at ordinary temperatures is very high, on the order of $10^{14}$ ohm-cm. Baked enamel should stand a temperature of 100 deg. cent. continuously without injury, but breaks down electrically at about 300 deg. cent. It is a fairly good thermal conductor and much superior to cotton and silk. An enameled wire should withstand bending around a mandrel four times its own diameter without injury. Turpentine, shellac, alcohol, vegetable or animal oils, and coal-tar solvents will attack it, but it is not injured by clean mineral oil and is moisture-proof. It should be carefully handled to avoid injuring the coating.

**352. Linseed oil** is a vegetable material derived from flaxseed, having a density of 0.932 to 0.936 at 15 deg. cent. It has excellent insulating properties and is extensively used in paints and varnishes. For specifications and general properties see "Year Book," A. S. T. M.; and Technologic Paper No. 9, Bureau of Standards, 1912. Boiled linseed oil has the property of oxidizing under ordinary exposure to air and the process will continue until it becomes viscous or even hard; the action can be hastened by drying agents and the application of heat.

**353. Ozokerite** (ozocerite) is a wax-like mineral, colorless or white when pure and consisting of a mixture of hydrocarbons. It is used in making ceresin, candles, etc. Crude ozokerite has a resistivity on the order of $4.5 \times 10^{14}$ ohm-cm. Liquid ozokerite has a dielectric constant of about 2.1. **Ceresin** is a yellow or white wax made by bleaching and purifying ozokerite and is employed as a constituent of insulating compounds; its density is 0.75; resistivity, over $5 \times 10^{16}$ ohm-cm. at 22 deg. cent.

**354. Paraffin** is a colorless or white waxy substance, consisting of a complex mixture of hydrocarbons, obtained by the distillation of wood, coal or oil. Chemically it is inert, being unaffected by most strong reagents. According to composition, it melts at from 45 to 80 deg. cent. and has a density of 0.87 to 0.94; resistivity, $10^{15}$ to $10^{18}$ ohm-cm.; dielectric constant, 1.9 to 2.3; dielectric strength, about 300 volts per mil; power-factor at 920 cycles, 0.0003.

**355. Resin** is defined as any of various solid or semi-solid organic substances, chiefly of vegetable origin, usually yellowish to brown in color, transparent or translucent, and soluble in ether, alcohol, etc., but not in water. They soften and melt on heating. Chemically they differ widely, but all are rich in carbon and hydrogen and contain also some oxygen. Among the commercial resins are amber, copal, dammar, guaiacum, lac, mastic, rosin and sandarac. Lac is the raw material used in making **shellac**, which has a resistivity on the order of $10^{15}$ to $10^{16}$ ohm-cm. and a dielectric constant of about 2.7 to 3.8.

**356. Wax** is defined as any of a class of natural substances composed of carbon, hydrogen and oxygen and consisting chiefly of esters other than those of glycerin or of free fatty acids. In this class are included beeswax, spermaceti, Chinese wax, carnauba wax, etc. Beeswax is a dull yellow solid, of density 0.96 to 0.97 at 15 deg. cent. and melting at 62 to 64 deg. cent.; resistivity, $10^{14}$ to $10^{17}$ ohm-cm.; dielectric strength, about 250 volts per mil.

**357. Weatherproof compounds** for saturating the cotton braids on weatherproof wire usually contain an asphaltum base, with an admixture of wax so that the surface of the braid may be given a dull polish.

## INSULATING OILS

**358. Oil** is employed as an insulating medium in many ways. It is employed by itself to insulate transformers and switches by immersion; it is used for saturating fibrous and other materials, as in cable work; drying oils (linseed) are used for coating papers and cloths in sheet insulation; various kinds of oil are employed in mixing insulating paints and varnishes. Oils of practically every variety are possessed of very high resistivity and dielectric strength. Chemically oil is composed of hydrocarbons having the general formulas $C_nH_{2n+2}$ and $C_nH_{2n}$. The desired characteristics of an insulating oil are high resistivity and dielectric strength, low viscosity, high flash point, chemical neutrality toward metals and insulating materials, freedom from moisture, sediment and impurities, and chemical stability under local high temperatures.

Digitized by Google

**359. Transformer oil.** The ideal cooling and insulating fluid for a transformer should have the characteristics named in Sec. 6, Par. 60. The oil largely used is a mineral oil obtained from crude petroleum by fractional distillation, having the following characteristics.

| | Medium | Light |
|---|---|---|
| Flash point, deg. cent. | 180 to 190 | 130 to 140 |
| Burning point, deg. cent. | 205 to 215 | 140 to 150 |
| Cold test | −10 to −15 | −15 to −20 |
| Density at 13.5 deg. cent. | 0.865 to 0.870 | 0.845 to 0.850 |
| Viscosity at 40 deg. cent. (Saybolt test) | 100 to 110 sec. | 40 to 50 sec. |
| Acid, alkali, sulphur, moisture | None | None |

When free from moisture the dielectric strength, between 0.5-in. discs 0.2 in. apart, with sine-wave e.m.f., should be from 45,000 to 50,000 volts; or between 0.5-in. brass spheres 0.15 in. apart the average dry oil should not break down at less than 30,000 volts. The medium grade of oil is usually employed in self-cooled apparatus and the light grade in water-cooled apparatus, but the dielectric strengths are the same. The dielectric strength between 0 and 100 deg. cent. increases about 0.4 to 0.5 per cent. per deg. The resistivity of dry oil is on the order of $10^{12}$ ohm-cm. and decreases with rise of temperature. The effect of moisture is very harmful (Par. 362) and it is of the greatest importance to keep oil absolutely dry or as nearly so as possible. One of the principal advantages of oil as an insulator is its property of self-restoration after dielectric discharge or puncture; this property is not independent, however, of the energy of discharge, and excessive energy may overheat the oil and cause explosion or fire. The specific heat of transformer oil is about 0.39 to 0.51 and the thermal conductivity ranges from 0.00033 to 0.00043 gram-calorie per cm-cube per deg. cent. per sec. The following references should be consulted for further information.

### 360. Electrical properties of oil

(Circular No. 36, U. S. Bureau of Standards, p. 24)

| Oil | Density at 20 deg. cent. | Resistivity (ohm-cm.) | Phase difference | | Dielectric constant |
|---|---|---|---|---|---|
| | | | 100 cycles | 1,200 cycles | |
| Pratts astral (kerosene). | 0.7852 | $470 \times 10^{12}$ | 0°2′11″ | 0°0′25″ | 2.34 |
| Paraffin | 0.8710 | $1{,}100 \times 10^{12}$ | 0°0′35″ | 0°0′ 5″ | 2.41 |
| Transformer oil (A) | 0.8795 | $0.49 \times 10^{12}$ | 1° 5′0″ | 0°5′10″ | 2.51 |
| Transformer oil (B) | 0.8682 | $3.1 \times 10^{12}$ | 0°30′0″ | 0°5′30″ | 2.47 |

**361. Dielectric strength** of oil with a 1-mm. gap (39.4 mils), expressed in volts per mm., is given in the table below for numerous varieties of oil.

| | | | |
|---|---|---|---|
| Castor | 13,000 | Neatsfoot | 9,000 |
| Cottonseed | 7,000 | Olive | 7,500 |
| Lard | 4,000 | Paraffin | 16,000 |
| Linseed, raw | 9,000 | Sperm, mineral | 8,500 |
| Linseed, boiled | 8,000 | Sperm, natural | 9,000 |
| Lubricating | 5,000 | Turpentine | 11,000 |

Digitized by Google

**362. Dielectric constants** of various kinds of oils are given in the accompanying table. The values probably change very appreciably with the temperature.

| | | | |
|---|---|---|---|
| Arachid | 3.17 | Petroleum | 2.02 to 2.19 |
| Castor | 4.6 to 4.8 | Rape seed | 2.2 to 3.0 |
| Colza | 3.07 to 3.14 | Sesame | 3.17 |
| Lemon | 2.25 | Sperm | 3.02 to 3.09 |
| Neatsfoot | 3.07 | Turpentine | 2.15 to 2.28 |
| Olive | 3.08 to 3.16 | Vaseline | 2.17 |

**363. Effects of moisture and dust on insulating properties of oil.** The presence of moisture in transformer oil has a very serious effect on the dielectric strength, as shown by Fig. 36. In order to obtain a dielectric strength of 40,000 volts (0.2-in. gap between 0.5-in. discs), the water present as distributed moisture in the oil must not exceed 0.001 per cent. Fine dust is also very injurious to the dielectric strength. For these reasons, various manufacturers have developed oil dryers and purifiers, which operate on the principle of a filter press.

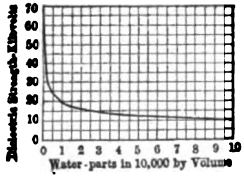

FIG. 36.—Effect of water on dielectric strength of oil.

**364. Formation of deposits in oil-cooled transformers.** The foregoing subject formed the title of a paper by Dr. A. C. Michie before the I. E. E. in April, 1913. The author stated that all oils oxidise in time, but the formation of deposits can be prevented or minimised by avoiding the following conditions: (1) Overheating; (2) undue access of air to the oil; (3) conditions likely to give rise to the formation of ozone; (4) contact of the oil with clean surfaces of copper, lead and iron.

**365. U. S. Government specification for transformer oil** calls for a pure mineral oil obtained by the fractional distillation of petroleum, unmixed with any other substance. It shall be prepared and refined especially for the purpose; shall be free from moisture, acid and alkali, and shall contain a minimum of sulphur compounds. The flash-point determined in a closed cup shall be not less than 170 deg. cent.; on cold test it shall not begin to solidify and no wax shall form in the oil above 0 deg. cent. It shall stand a breakdown test of 30,000 volts between spheres of 0.5 cm. radius, 0.40 cm. apart. See Circular No. 22, Bureau of Standards, 1911.

## GASES

**366. The insulating properties of gases** depend upon, and vary with, the pressure and the temperature, and are affected also by the humidity. The only gaseous dielectric in extensive use is atmospheric air, whose properties have been the subject of extended research.

**367. Air.** The dielectric properties of air, and particularly its disruptive strength, have been the subject of more investigation than any other dielectric in use. Extended investigations and researches have been made by Ryan, Mershon, Fisher, Peek, Whitehead, Faccioli, Harding, Bennett, Fortescue and Farnsworth, whose results have been published during the past 10 years in the *Trans.* A. I. E. E., and by Russell (see *Jour.* I. E. E.).

Air in the free state has electrical conductivity. The results obtained (see Whitehead, *Proc.* A. I. E. E., May, 1915, p. 846) indicate that in the open the current passing between two parallel plates 10 cm. apart and each 100 cm. square, assuming perfect insulation, would be of the order of magnitude $3 \times 10^{-16}$ amp. This is the maximum current which may be obtained and does not increase with increase of voltage; it diminishes greatly if the air is confined in a closed vessel. The conductivity may be greatly increased by exposing the air to Röntgen rays, ultra-violet light, etc., but the magnitude of current still remains very small.

The dielectric constant of air is usually taken as unity, and air is almost universally the medium of reference in all measurements of this constant.

Digitized by Google

The disruptive strength of air in a uniform, electrostatic field, under most favorable conditions, at ordinary temperature and pressure, is of the order of 38 kv. per cm. or 97 volts per mil (maximum instead of r.m.s. value); Whitehead found a value of 32 kv. (max.) and Peek found a value of 30 kv. (max.). Under unfavorable conditions, the strength is below 30 kv. max (21 kv., r.m.s.), as shown by investigations of corona on cylindrical wires (see Sec. 11). The disruptive strength is directly proportional to the air density, over a considerable range. If the air density at 76 cm. barometer and 25 deg. cent. is taken as unity, the relative density at any other pressure and temperature is

$$\delta = \frac{3.92b}{273 + t} \qquad (20)$$

where $b$ is the barometer in cm. and $t$ is the temperature in deg. cent. Apparently the degree of humidity has very often little, if any, effect on the disruptive strength.

Advantage is taken of the low disruptive strength of air at low pressures (small fraction of one atmosphere) in so-called vacuum-type lightning arresters, recently developed for low-voltage, low-power circuits, such as telephone, telegraph and signal lines.

Sparking distances in air, using needle gaps and sphere gaps, are given in the A. I. E. E. Standardisation Rules, Sec. 24, Par. 274 to 276.

**368. Relative disruptive strengths of hydrogen, oxygen, carbon dioxide and nitrogen**
(Wolf)

| Pressure in atmospheres | Relative strength (air = 1) | | | | |
|---|---|---|---|---|---|
| | Hydrogen | Oxygen | Air | Carbon dioxide | Nitrogen |
| 1 | 0.87 | 0.95 | 1.00 | 1.20 | 1.16 |
| 2 | 0.76 | 0.93 | 1.00 | 1.10 | 1.15 |
| 3 | 0.72 | 0.92 | 1.10 | 1.05 | 1.15 |
| 4 | 0.69 | 0.92 | 1.00 | 1.03 | 1.14 |
| 5 | 0.68 | 0.90 | 1.00 | 1.02 | 1.14 |

## THERMAL CONDUCTIVITIES

**369. Thermal conductivities of various insulating materials**
(Langmuir, I., *Trans.* A. I. E. E., 1913, Vol. XXXII, p. 303)

| Material | Watt-cm. per deg. cent. | Material | Watt-cm. per deg. cent. |
|---|---|---|---|
| Air at 20 deg. cent. | 0.000249 | Mica, pure | 0.0036 |
| Air at 100 deg. cent. | 0.000300 | Mica paper | 0.0016 |
| Asbestos paper | 0.0025 | Micanite (19 per cent shellac) | 0.0010 |
| Bakelite and linen tape | 0.0027 | Micanite (11 per cent. shellac) | 0.0012 |
| Cambric, varnished | 0.0025 | Paper | 0.0013 |
| Cloth, varnished (empire) | 0.0025 | Paraffin | 0.0026 |

# STRUCTURAL MATERIALS

## CAST IRON

**371. Cast iron** derives its characteristic qualities from the impurities present. These impurities are the same as those in steel, except for graphite, which is one form of carbon. The carbon is always present in two forms: (1) combined carbon, in the form of cementite; (2) uncombined carbon, or graphite. The total carbon seldom exceeds. 4.5 per cent. or falls below 3.25 per cent. The larger the proportion of carbon in the combined state, the harder and more brittle will be the metal. Cast iron is not ductile, in either hot or cold state.

Silicon is a desirable impurity, because it tends to precipitate carbon in the graphitic form; about 3 per cent. of silicon gives the best results. Sulphur has the opposite effect of silicon, and is undesirable. Managnese increases the total carbon and also the proportion of combined carbon, but tends to neutralise the similar effect of sulphur. Phosphorus, if present in sufficient proportions to be chemically active, tends to hold the carbon in combined form, and also tends to weaken the metal.

**372. White cast iron.** If slowly cooled, white cast iron will contain combined carbon in the form of cementite, which imparts the qualities of hardness and brittleneess to the metal. Where the carbon is from 3 to 4 per cent., cementite will form from 45 to 50 per cent. of the material. Unless the cooling is slow some of the carbon will be in the austenitic form. White cast iron has few uses, except as a hard coating or skin for gray iron castings.

Digitized by Google

**373. Gray cast iron** usually contains 2 per cent. or more of graphite and less than 1.5 per cent. of combined carbon. The graphite is mechanically intermingled throughout the body of the metal; although the percentage by weight may be no more than 4 per cent., the percentage by volume may be as much as 14 per cent. The smaller the proportion of combined carbon, the larger will be the proportion of graphite and the softer and more workable the metal; at the same time this produces a metal of minimum strength, because of its porosity. The interstices are filled with graphite, which acts in a degree as a lubricant in machining operations.

**Chilled castings** are made by pouring cast iron into a metallic mold which cools it rapidly near the surfaces of the casting, thus forming a skin of harder material than the body of the metal. The rapid cooling decreases the proportion of graphite and increases the combined carbon, resulting in the formation of white cast iron.

**374. Density of cast iron.** Stoughton gives the following densities: pure iron, 7.86; white cast iron, 7.60; mottled cast iron, 7.35; light gray cast iron, 7.20; dark gray cast iron, 6.80.

**375. Strength of cast iron.** (Stoughton)

| | Composition | | | | Tensile strength (lb. per sq. in.) |
|---|---|---|---|---|---|
| | Silicon (per cent.) | Sulphur (per cent.) (max.) | Phosphorus (per cent.) (max.) | Manganese (per cent.) | |
| Soft | 2.2 to 2.8 | 0.085 | 0.70 | 0.3 to 0.7 | 28,000 |
| Medium | 1.4 to 2.0 | 0.085 | 0.70 | 0.3 to 0.7 | 30,000 |
| Hard | 1.2 to 1.9 | 0.085 | 0.7 to 0.4 | 0.60 | 25,000 |

The total range of tensile strength, taking into account all grades of cast iron, is from about 15,000 to 40,000 lb. per sq. in. The compressive strength is from about 60,000 to 150,000 lb. per sq. in. Young's modulus also varies considerably, an average value being about $15 \times 10^6$ lb. per sq. in. Also see "Reports of Tests of Metals" (Watertown Arsenal), Gov. Printing Office, Wash. D. C.; annually.

**376. Thermal properties.** The average specific heat from 20 to 100 deg. cent. is 0.119; thermal conductivity, 0.40 watt-cm. per deg. cent.; coefficient of linear expansion, 0.0000106 per deg. cent., at 40 deg. cent.

**377. Malleable cast iron.** Iron castings in which the majority of the carbon content is in combined form are annealed at 625 to 875 deg. cent. for about 60 hr. The combined carbon is thereby reduced to graphite, which occurs in finely powdered form; in the skin of the metal the carbon is eliminated entirely, leaving countless minute cavities. When the castings are made very thin and annealed for a longer period, the carbon can be removed entirely. If the castings are annealed in lime or fireclay, the carbon is not removed, but deposited as temper carbon. The physical properties lie in the range between gray cast iron and steel castings. The tensile strength ranges between 40,000 and 60,000 lb. per sq. in., with an elongation of 2 to 6 per cent. and a reduction of area of 2 to 8 per cent.

## WROUGHT IRON

**378. Pure iron,** according to Stoughton, has a tensile strength of about 45,000 lb. per sq. in. and a compressive strength of about 80,000 lb. per sq. in. The specific gravity is 7.86.

**379. Ingot iron,** as it recently has become known in this country, is commercially pure iron manufactured by the basic open-hearth process, and it is claimed that the iron content ranges from 99.8 to 99.9 per cent. The tensile strength of rolled material is from 42,000 to 44,000 lb. per sq. in.; elastic limit, 25,000 lb. per sq. in.; elongation, 25 per cent. in 8 in.

**380. Thermal properties.** The mean specific heat from 0 to 18 deg. cent. is 0.0986; 15 to 100 deg., 0.115. Thermal conductivity, at 0 deg. cent., 0.167 to 0.207 g-cal. (cm-cube) per deg. cent. per sec.; at 18 deg. cent.,

Digitized by Google

0.67 watt-cm. per deg. cent., for pure iron. Coefficient of linear expansion, 0.0000114 per deg. cent., between −18 and 100 deg. cent.

**381. Electrolytic iron melted in vacuo,** forged into half-inch rods and annealed at 900 deg. cent., has the following average tensile properties.

| | Tensile strength (lb. per sq. in.) | Yield point (lb. per sq. in.) | Elongation (per cent.) | Reduction of area (per cent.) |
|---|---|---|---|---|
| As forged | 54,800 | 48,400 | 33.3 | 83.0 |
| Annealed at 900 deg. cent. and cooled in 12 hr. | 38,100 | 18,000 | 51.8 | 87.4 |

The average carbon content of this iron was 0.0125 per cent. See Bulletin No. 72, Eng. Exp. Sta., Univ. of Ill., 1914.

**382. Tensile properties of wrought iron.** The following properties were taken from Campbell's "Manufacture and Properties of Iron and Steel," 4th edition, p. 91. Also see Holley, "The Strength of Wrought Iron as Affected by its Composition and its Reduction in Rolling," *Trans.* A. I. M. E., Vol. VI, p. 101.

| | Minimum | Maximum |
|---|---|---|
| Carbon, per cent | 0.015 | 0.512 |
| Phosphorus, per cent | 0.065 | 0.317 |
| Silicon, per cent | 0.028 | 0.321 |
| Manganese, per cent | trace | 0.097 |
| Slag, per cent | 0.192 | 2.262 |
| Ultimate strength, lb. per sq. in. | 47,478 | 69,779 |
| Elongation in 8 in., per cent | 6.5 | 32.7 |
| Reduction of area, per cent | 7.7 | 59.8 |

The general influence of reduction in rolling is to increase the tensile strength and the elastic limit, and diminish the elongation and the reduction of area.

## STEEL

**383. Carbon steel.** Increasing the carbon content of steel increases its strength, hardness, brittleness, and susceptibility to cracking under sudden cooling or heating; it also diminishes the elongation and reduction of area at fracture. In acid steel, according to Campbell, each 0.01 per cent. of carbon increases the strength by 1,000 lb. per sq. in., when the carbon is determined by combustion; or 1,140 lb. per sq. in. when the carbon is determined by color. In basic steel each 0.01 per cent. of carbon increases the strength by 770 lb. per sq. in., when the carbon is determined by combustion, or 820 lb. when determined by color.

**Phosphorus** increases the tensile strength 1,000 lb. per sq. in. for each 0.01 per cent., but tends to make the metal "cold short" or brittle. **Sulphur** does not alter the tensile strength appreciably, but tends to make the metal "hot short." **Manganese** increases the tensile strength from 80 to 400 lb. per sq. in. for each 0.01 per cent., depending upon the carbon present, and whether the steel is acid or basic; it also increases the ductility when hot. **Silicon** in small quantities has little effect. **Copper** has also little effect on the cold properties as far as known. **Nickel** gives a metal with a high elastic limit and great toughness under shock. **Aluminum** in small quantities is added to molten steel to absorb oxygen and improve the fluidity; when present in the finished metal it increases the strength and impairs the ductility.

The thermal conductivity of steel containing 1 per cent. of carbon, at 18 deg. cent., is 0.45 watt-cm. per deg. cent. The coefficient of linear expansion ranges between 0.0000104 and 0.0000132 per deg. cent.

Digitized by Google

**384. Effect of hot working.** The effect of hot-rolling or hammering carbon steel is in general to increase the tensile strength and the elastic limit, and to diminish the elongation and the reduction of area at fracture.

**385. Annealing** carbon-steel tends to remove the strains created by cold rolling and distortion. In general the effects of annealing are: reduction of tensile strength, elastic limit, and elastic ratio; increase in elongation and reduction of area at fracture. In short, the process of annealing tends to restore the original properties, and to improve the grain or structure.

**386. Heat treatment.** The finer the grain or structure of steel, in general, the better will be the physical properties. When steel is heated to rolling or forging temperature, the crystalline structure is coarsened, but hot working tends to improve the structure. The best results are obtained by reheating the finished steel to a temperature of about 800 to 900 deg. cent. and allowing it to cool slowly (annealing); the best temperature in any instance depends upon the constituents of the steel. The proper heat treatment of steel is virtually an art in itself.

**387. Hardening and tempering.** When carbon-steel is heated to a medium red and quenched in water or oil it acquires the maximum hardness, becomes brittle, and loses its ductility. The increase in tensile strength due to hardening will vary from about 10 per cent. in steel containing 0.10 carbon to 40 per cent. in steel containing 0.75 carbon. Hardened steel is usually too brittle for practical use, and requires softening by drawing the temper; this is accomplished by slowly reheating the steel until its color changes from white to the proper shade, ranging anywhere from straw (high temper) to purple (low temper).

**388. Chrome steel** contains usually from 1 to 2 per cent. of chromium and 0.80 to 2 per cent. of carbon. It is characterized by great hardness and high elastic ratio. See "Magnet Steel," Sec. 4.

**389. Manganese steel.** Hadfield* found that the addition of from 2.5 to 6 per cent. of manganese to steel made the product very brittle, but after the proportion exceeded 7 per cent. there was a return of strength and at 14 to 15 per cent. of manganese a very strong hard alloy was obtained; above 20 per cent. a rapid decrease occurs in strength and toughness. In its most serviceable form, manganese steel contains about 13 to 14 per cent. of manganese, and is practically non-magnetic; on account of its extreme hardness, it is almost impossible to work it with machine tools and it must be cast in the approximate form in which it is to be used. Heating to 1,800 deg. to 2,000 deg. cent. and quenching in cold water, or "water toughening," increases the hardness and resistance to fracture; this is true of both cast and forged material. An alloy of 87 per cent. iron, 12 per cent. manganese and 1 per cent. carbon has a magnetic permeability between 1.3 and 1.5.† The hardness is due partly to the hardness of manganese, and also in large degree to the fact that the steel is in the austenitic condition, which renders it non-magnetic. On account of its hardness it must be cast in the desired form, since it cannot be machined and can be forged only with difficulty.

**390. Nickel steel** ordinarily contains 1.5 to 4.5 per cent. of nickel and 0.20 to 0.50 per cent. of carbon. About 3.5 per cent. of nickel added to carbon-steel will increase the elastic limit nearly 50 per cent. and reduce the ductility about 15 or 20 per cent. The tensile strength is increased also, but not in as large proportion as the elastic limit. The notable increase in elastic limit and elastic ratio is accompanied by an increased resistance to fatigue under repeated stress. In low-carbon steels, the addition of each 1 per cent. of nickel, up to 5 per cent., increases the elastic limit 5,000 lb. per sq. in. and the tensile strength 4,000 lb. per sq. in.; these effects increase with higher percentages of carbon. The resistance to compression is also greater. The value of Young's modulus is the same as for carbon-steel. Nickel steel has a higher resistance to wear or abrasion than carbon-steel, and greater resistance to corrosion. Special alloys very high in nickel are known as Invar and Platinite; **Invar** contains 36 per cent. of nickel and its coefficient of expansion

*Hadfield, R. A. *Trans.* Amer. Inst. of Mining Eng., 1893, Vol. XXIII, p. 148; *Jour.* Iron and Steel Inst., 1888, No. 2, p. 41; *Proc.* Inst. of Civ. Eng., 1887–1888, Vol. XCIII, Part 3, p. 1.
Hall, J. H. "Manganese Steel," *Proc.* Soc. of Chem. Industry, 1914.
†Ewing, J. A. "Magnetic Induction in Iron and Other Metals."

Digitized by Google

is practically zero. **Platinite** (42 per cent. Ni) has the same coefficient of expansion as glass. See Colby, A. L. "Nickel Steel," *Proc.* A. S. T. M., Vol. III, 1903.

**391. Silicon steel.*** The addition of silicon to steel appears to increase the strength about 80 lb. per sq. in. for every 0.01 per cent., up to a content of 4 per cent.; beyond this point it severely impairs the ductility. A steel containing 3.40 silicon, 0.21 carbon and 0.29 manganese had a tensile strength of 106,000 lb. per sq. in.; elastic ratio, 0.74; elongation, 11 per cent.; reduction of area, 14 per cent.; annealed strength, 87,000 lb. per sq. in. Silicon is used in electrical sheets, because it substantially increases the electrical resistivity and thus reduces the core loss; such sheets are much harder than ordinary dynamo sheets of soft steel; see "Magnetic Materials" in this section. The thermal conductivity of 4 per cent. silicon-steel, between 20 and 250 deg. cent., is 0.32 watt-cm. per deg. cent.

**392. Tungsten steel** is characterized by great hardness and toughness and its remarkable tempering properties. The tungsten content ranges from 0.5 per cent. in ordinary bar steel to 2 to 5 per cent. in finishing and intermediate steels, 4.5 to 12 per cent. in self-hardening or air-hardening steels, and 14 to 26 per cent. in high-speed steels. See Baskerville, C. "The Chemistry of Tungsten, Etc.," *Trans.* N. Y. Elec. Soc., Oct. 29, 1912; also see "Magnet Steel," Sec. 4.

**393. Vanadium steel.** The use of vanadium as an alloy with steel produces more remarkable results than any other element except carbon. Oil-tempered vanadium steel containing 0.25 to 0.30 carbon, 0.50 manganese, 1.0 chromium and 0.17 vanadium has been found to have a tensile strength as high as 233,000 lb. per sq. in., elastic ratio 96 per cent., elongation 11 per cent., and contraction of area 39 per cent. The vanadium content is usually less than 0.3 per cent.; its effect in general is to improve the tensile properties, hardness and toughness.

**394. Protective coatings** for iron and steel consist of the following: (a) pigments of various kinds; (b) galvanising or zinc coating, applied by hot-dipping, electroplating or dry-heating with zinc dust; (c) coating with aluminum alloy, by dry-heating with the powdered alloy; (d) tinning, by hot-dipping and rolling; (e) terne coating, of lead-tin alloy, applied in the same manner as tinning; (f) nickel-plating, applied electrolytically; (g) coating of black oxide of iron, produced by application of oil to the metal when black hot; (h) enamel coating of glass. For out-door exposures, methods (a) and (b) are the ones chiefly used, but neither is free from faults or objections. For particulars see Wood, M. P. "Rustless Coatings; Corrosion and Electrolysis of Iron and Steel," New York, 1905; "Report of the Committee on Preservative Coatings for Structural Materials," 1903 to 1913, A. S. T. M., Phila., Pa.; Bulletins No. 30, 35 and 239, U. S. Dept. of Agriculture, Wash., D. C. Stoughton, B. "The Metallurgy of Iron and Steel," McGraw-Hill Book Co., Inc., New York, 1911. | 12 | 0.105 | 0.008659 | 866 | 29.1 | 154 |
| 13 | 0.092 | 0.006648 | 665 | 22.3 | 118 |
| 14 | 0.080 | 0.005027 | 503 | 16.9 | 89.2 |
| 15 | 0.072 | 0.004071 | 407 | 13.7 | 72.2 |

This table was calculated on a basis of 483.84 lb. per cu. ft. for steel wire. Iron wire is a trifle lighter. The breaking loads were calculated for 100,000 lb. per sq. in. throughout, simply for convenience, so that the breaking loads of wires of any strength per sq. in. may be quickly determined by multiplying the values given in the table by the ratio between the strength per sq. in. and 100,000. As a matter of fact the strength ranges from 45,000 lb. for soft annealed to over 400,000 lb. per sq. in. for hard wire.

**396. Galvanized steel signal wire** in sizes of No. 8 and No. 9 B.W.G. is manufactured (Amer. Steel and Wire Co.) with approximate breaking strengths of 2,350 lb. and 1,900 lb., respectively. It is used for operating semaphore signals from levers in a mechanical interlocking machine (Sec. 16).

**397. Table of galvanized steel cable or messenger strand; standard steel, open-hearth steel, crucible steel and plow steel**

(American Steel and Wire Co.)

| Diam. (in.) | Lb. per 1,000 ft. | Ultimate total strength (lb.) | | | |
|---|---|---|---|---|---|
| | | Standard steel strand | Siemens-Martin (open-hearth) strand | High-strength (crucible steel) strand | Extra high-strength (plow steel) strand |
| 1 | 2,250 | ..... | 51,000 | 87,400 | 120,000 |
| $\frac{7}{8}$ | 1,700 | ..... | 38,000 | 64,000 | 90,000 |
| $\frac{3}{4}$ | 1,250 | ..... | 28,400 | 47,400 | 70,000 |
| $\frac{5}{8}$ | 810 | ..... | 19,000 | 25,000 | 42,500 |
| $\frac{9}{16}$ | 510 | 8,500 | 11,000 | 18,000 | 27,000 |
| $\frac{1}{2}$ | 415 | 6,500 | 9,000 | 15,000 | 22,500 |
| $\frac{7}{16}$ | 295 | 5,000 | 6,800 | 11,500 | 17,250 |
| $\frac{3}{8}$ | 210 | 3,800 | 4,860 | 8,100 | 12,100 |
| $\frac{5}{16}$ | ..... | ..... | 4,380 | 7,300 | 10,900 |
| $\frac{1}{4}$ | 125 | 2,300 | 3,060 | 5,100 | 7,600 |
| $\frac{3}{16}$ | 95 | 1,800 | ..... | ..... | ..... |
| $\frac{1}{8}$ | 75 | 1,400 | 2,000 | 3,300 | 4,900 |

A special $\frac{1}{8}$-in. Siemens-Martin strand is manufactured, having an ultimate strength of 6,000 lb.

**398. Tensile tests of steel spring wire,** of best quality tempered music-wire, from about 0.04 to 0.05 in. in diameter, gave from 342,000 to 388,000 lb. per sq. in.; elongation between 1 and 2 per cent.; contraction of area, 38 to 46 per cent. (Report of Tests of Metals, 1904; Watertown Arsenal).

## NON-FERROUS METALS AND ALLOYS

**399. Properties of miscellaneous non-ferrous metals and alloys**

(Compiled from various authorities)

| Metal | Density | Strength (1,000 lb. per sq. in.) | | Young's modulus ($10^6$ lb. per sq. in.) | Coefficient of expansion per deg. cent. $\times 10^{-6}$ | Thermal conductivity (g-cal. per cm-cube per deg. cent. per sec.) |

## CONCRETE, BRICK AND STONE

**400. The composition of normal Portland cement*** has been the subject of a great deal of investigation and it can be said that the quantities of silica, alumina, oxide of iron, lime, magnesia, and sulphuric anhydride can vary within fairly wide limits without materially affecting the quality of the material. A normal American Portland cement which meets the standard specifications for soundness, setting time and tensile strength has an approximate composition within the following percentage limits:

| | | | |
|---|---|---|---|
| Silica | 19–25 | Magnesia | 1–4 |
| Alumina | 5–9 | Sulphur trioxide | 1–1.75 |
| Iron oxide | 2–4 | Loss on ignition | 0.5–3.00 |
| Lime | 60–64 | Insoluble residue | 0.1–1.00 |

It is also true that a number of cements have been made both here and abroad which have passed all standard physical tests in which these limits have been exceeded in one or more particulars, and it is equally true that a sound and satisfactory cement does not necessarily result from the above composition. Defective cement usually results from imperfect manufacture, not from faulty composition. Cement made from very finely ground material, thoroughly mixed and properly burned, may be perfectly sound when containing more than the usual quantity of lime, while a cement low in lime may be entirely unsound due to careless manufacture. Also see Sec. 15, Par. 265 *et seq.*

**401. Standard methods of testing cement** are described in Circular No. 33, Bureau of Standards, pages 9 to 28. Also see circular No. 39, *in re* standard sieves.

**402. Neat cement** is Portland cement mixed with enough water to work it, and without the use of any aggregates (sand, gravel or stone). When such a mixture is made thin enough to pour, it is termed **grout**. Neat cement is employed in cementing together parts of large porcelain insulators, or cementing the insulators to their supporting members.

**403. Crushing strength of concrete.** (Smithsonian Phys. Tables, 1910; based on data furnished by the U. S. Geol. Survey.)

| Coarse aggregate | Proportions by volume: cement-sand-aggregate | Lb. per sq. in. |
|---|---|---|
| Sandstone | 1–5–14 to 1–1–5 | 1,550 to 3,860 |
| Cinders | 1–3– 6 to 1–1–3 | 790 to 2,050 |
| Limestone | 1–4– 8 to 1–2–4 | 1,200 to 2,840 |
| Conglomerate | 1–6–12 to 1–2–4 | 1,080 to 3,830 |
| Trap | 1–2– 9 to 1–2–4 | 820 to 2,960 |

Test pieces were 12-in. cubes. Also see Bulletins of Eng. Exp. Sta., Univ. of Ill.; publications of the Geological Survey; publications of the Bureau of Standards.

**404. Weight of concrete.** The weight of stone and gravel concrete, 1:2:4 mixture, may be taken as 150 lb. per cu. ft.; cinder concrete, 120 lb.

**405. Reinforced concrete.** See Sec. 23, Par. 12 to 17 and Par. 24.

**406. Crushing strength of brick.** (Smithsonian Phys. Tables, 1910; based on data furnished by the U. S. Geol. Survey.)

| Kind of brick | Lb. per sq. in. | |
|---|---|---|
| | Tested flatwise | Tested on edge |

Brick piers laid up in 1 part Portland cement, and 3 of sand, have from 20 to 40 per cent. of the crushing strength of the brick. Also see "Report of Tests of Metals," Gov. Printing Office, Washington, D. C., 1909.

**407. Fire-brick** when tested on end, at atmospheric temperature, should exhibit a crushing strength of more than 1,000 lb. per sq. in. More important is the ability to withstand a compression load of 50 lb. per sq. in. at 1,350 deg. cent. without failure; if the specimen shows marked deformation or contracts more than 1 in. in the standard length of 9 in., failure is considered to have taken place. Fire-brick should have average melting points as follows, in deg. cent.: fire clay, 1,650; bauxite, 1,695; silica, 1,700; chromite, 2,050; magnesia, 2,165.

**408. Clay tile.** The strength of drain tile is covered by standard specifications of the A. S. T. M. (see "Year Book"). Also see Bulletins No. 31 and No. 36, Iowa Eng. Exp. Sta., Ames, Ia.

**409. Crushing strength of stone.** (Smithsonian Phys. Tables, 1910; based on data furnished by U. S. Geol. Survey.)

| Material | Size | Lb. per sq. in. |
|---|---|---|
| Marble | 4-in. cubes | 7,600 to 20,700 |
| Brownstone | | 7,300 to 23,600 |
| Sandstone | 4-in. cubes | 2,400 to 29,300 |
| Granite | 4-in. cubes | 9,700 to 34,000 |
| Limestone | 4-in. cubes | 6,000 to 25,000 |

## TIMBER

**410. Wood** consists of a skeleton of cellulose permeated by a mixture of other organic substances collectively known as lignum, and particles of mineral matter (or ashes). Wood dried at 300 deg. fahr. is comprised of more than 99 per cent. organic matter, and less than 1 per cent. inorganic or non-combustible matter. In 100 lb. of wood dried at 300 deg. fahr. will be found about 49 lb. of carbon, 6 lb. of hydrogen and 44 lb. of oxygen; the composition is fairly uniform for the different species.

**411. Spring wood and summer wood** in coniferous trees are distinguished by the different colors in each ring. The inner light-colored portion of a ring is termed the spring wood, and the outer dark-colored portion is the summer wood. In oak and other broad-leaved woods, however, the darker portions are the spring wood and the lighter parts are summer wood.

**412. Annual or yearly concentric rings** which appear at the cross-section of a log are so many thin layers of wood, forming a consecutive series of enveloping cones, each ring or cone representing one year's growth. As a rule the rings are widest near the pith or centre of the tree.

**413. Sapwood and heartwood.** A zone of wood next to the bark, 1 in. to 3 in. or more wide, of light color and containing 30 to 50 or more annual rings, is the sapwood; the darker central portion is the heartwood. Only the outer portions of the sapwood assist in the growing processes and ultimately the sapwood changes to heartwood. The cells of the latter are lifeless and serve merely a structural function. The proportion of sapwood in coniferous trees constitutes 40 per cent. or more of the bulk, and a much larger proportion in young trees.

**414. Moisture in wood.** Water occurs in wood in three forms: (1) It forms the greater part (over 90 per cent.) of the protoplasmic contents of the living cells; (2) it saturates the walls of all cells; (3) it wholly or partly fills the cavities of the lifeless cells. In drying green wood in a kiln, from 40 to 65 per cent. of the weight of the sapwood and 16 to 40 per cent. of the weight of the heartwood are lost as excluded moisture. The weight is obviously dependent in large degree on the extent of seasoning or drying.

**415. Shrinkage** takes place as green wood is dried, but does not commence until the fibre saturation point is reached; then it commences to shrink both laterally and longitudinally, but the latter in most species is negligible. The shrinkage of transverse area in drying from green to oven-dry condition (3.5 per cent. of moisture) varies with different species from as much as 20 per cent. with hickory to as low as 7 per cent. with red cedar. The radial

Digitized by Google

shrinkage in poles is usually small; the circumferential shrinkage in chestnut poles 1 year after cutting has been found not to exceed 1 per cent.

**416. Specific gravity and fibre saturation point.** The following table was abstracted from Circular No. 108, "The Strength of Wood as Influenced by Moisture," by H. D. Tiemann, U. S. Forest Service, p. 11.

| Species (small test specimens) | Average density (kiln-dry) | Per cent. moisture at fibre saturation |
|---|---|---|
| Long-leaf pine | 0.62 | 25 |
| Red spruce | 0.38 | 31 |
| Chestnut | 0.48 | 25 |
| Loblolly pine, green heartwood | 0.59 | 23 |
| Loblolly pine, air-dry heartwood | 0.67 | 24 |
| Loblolly pine, green sapwood | 0.47 | 24 |
| Loblolly pine, air-dry sapwood | 0.55 | 26 |
| White ash | 0.79 | 20 |
| Red gum, air-dry | 0.52 | 25 |
| Douglas fir | 0.58 | 23 |
| Norway pine, heartwood | 0.42 | 30 |
| Norway pine, sapwood | 0.44 | 28 |
| Tamarack | 0.54 | 30 |

**417. Specific heat** of oven-dry wood, based on 100 determinations with 20 different species, was found to be represented by the formula

$$\text{Sp. heat} = 0.266 + 0.00116t \qquad (21)$$

for a range from 0 deg. to 106 deg. cent. The average was 0.327, with a maximum of 0.337 (for longleaf pine) and a minimum of 0.317 (for chestnut). The material tested showed a variation of from 3 to 20 rings per cm. and a range of 0.40 to 0.59 in density. See Bulletin No. 110, U. S. Forest Service; 1912.

**418. Standard names and standard defects of structural timber** were defined and adopted by the Amer. Soc. for Testing Materials, on Sept. 1, 1907; see "Year Book."

**419. Effect of moisture on strength.** Moisture is found in green wood in two states—that which is in the walls of the cells and that which fills the pores. The latter has no influence on the strength. The point at which the cell walls become saturated with water, although the pores may continue to absorb it, is termed the **fibre saturation point.** When the absorption of moisture continues past the fibre saturation point, there is no further swelling of the wood and no further effect upon the strength.

Green timber is in general weaker than seasoned or dry timber, except as to shearing resistance parallel to the grain. While reduction of the moisture content tends of itself to increase the strength, the seasoning process also has a counter-tendency or weakening effect which results from the formation of checks. The increase in strength due to drying is especially marked in small pieces free from defects, but large timbers almost invariably form checks during seasoning and it is not in general safe to count upon any increase in strength. In the case of structural timbers it is safest always to determine the strength from tests on pieces of the size and in the condition in which they will be used. For further particulars see Bulletin No. 70, Bulletin No. 108 and Circular No. 108, U. S. Forest Service, Wash., D. C.

**420. Working unit stresses for structural timber,** as adopted by the American Railway Engineering Association, are given in the table below. The working unit stresses given in the table are intended for railroad bridges and trestles. For highway bridges and trestles, the unit stresses may be increased 25 per cent. For buildings and similar structures, in which the timber is protected from the weather and practically free from impact, the unit stresses may be increased 50 per cent. To compute the deflection of a beam under long continued loading instead of that when the load is first applied, only 50 per cent. of the corresponding modulus of elasticity given in the table is to be employed.

**Working unit stresses for structural timber (Par. 420)**
(Unit stresses in pounds per square inch)

| Kind of timber | Bending | | | Shearing | | | | Compression | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | Extreme fiber stress | | Modulus of elasticity | Parallel to the grain | | Longitudinal shear in beams | | Perpendicular to the grain | | Parallel to the grain | | Working stresses for columns | |
| | Average ultimate | Working stress | Average | Average ultimate | Working stress | Average ultimate | Working stress | Elastic limit | Working stress | Average ultimate | Working stress | Length under 15×d | Length over 15×d |
| Douglas Fir | 6100 | 1200 | 1510000 | 690 | 170 | 270 | 110 | 630 | 310 | 3600 | 1200 | 900 | 1200 $(1-L/60D)$ |
| Long-leaf Pine | 6500 | 1300 | 1610000 | 720 | 180 | 300 | 120 | 520 | 260 | 3800 | 1300 | 975 | 1300 $(1-L/60D)$ |
| Short-leaf Pine | 5600 | 1100 | 1480000 | 710 | 170 | 330 | 130 | 340 | 170 | 3400 | 1100 | 825 | 1100 $(1-L/60D)$ |
| White Pine | 4400 | 900 | 1130000 | 400 | 100 | 180 | 70 | 290 | 150 | 3000 | 1000 | 750 | 1000 $(1-L/60D)$ |
| Spruce | 4800 | 1000 | 1310000 | 600 | 150 | 170 | 70 | 370 | 180 | 3200 | 1100 | 825 | 1100 $(1-L/60D)$ |
| Norway Pine | 4200 | 800 | 1190000 | 590* | 130 | 250 | 100 | ..... | 150 | 2600* | 800 | 600 | 800 $(1-L/60D)$ |
| Tamarack | 4600 | 900 | 1220000 | 670 | 170 | 260 | 100 | ..... | 220 | 3200* | 1000 | 750 | 1000 $(1-L/60D)$ |
| Western Hemlock | 5800 | 1100 | 1480000 | 630 | 160 | 270* | 100 | 440 | 220 | 3500 | 1200 | 900 | 1200 $(1-L/60D)$ |
| Redwood | 5000 | 900 | 800000 | 300 | 80 | ..... | ..... | 400 | 150 | 3300 | 900 | 675 | 900 $(1-L/60D)$ |
| Bald Cypress | 4800 | 900 | 1150000 | 500 | 120 | ..... | ..... | 340 | 170 | 3900 | 1100 | 825 | 1100 $(1-L/60D)$ |
| Red Cedar | 4200 | 800 | 800000 | ..... | ..... | ..... | ..... | 470 | 230 | 2800 | 900 | 675 | 900 $(1-L/60D)$ |
| White Oak | 5700 | 1100 | 1150000 | 840 | 210 | 270 | 110 | 920 | 450 | 3500 | 1300 | 975 | 1300 $(1-L/60D)$ |

Unit stresses are for green timber and are to be used without increasing the live load stresses for impact. Value noted * are for partially air-dry timber. In the formulas given for columns, $L$ = length of column, in inches, and $D$ = least side or diameter, in inches.

**421. Tests of maple and hickory**
(Lb. per sq. in.)

| | Elastic limit | | | Maximum load | | |
|---|---|---|---|---|---|---|
| | Aver. | Max. | Min. | Aver. | Max. | Min. |
| Maple..... | 8895 | 9950 | 7370 | 14,130 | 17,600 | 9,800 |
| Hickory..... | 8063 | 9150 | 7440 | 16,000 | 17,100 | 13,900 |

See Circular No. 42 and Bulletin No. 80, U. S. Forest Service, Wash., D. C.

**422. Standard specifications for yellow-pine bridge and trestle timbers** were adopted in 1910 by the Amer. Soc. for Testing Materials; see 1914 "Year Book," pp. 352 to 354.

**423. Weight and seasoning of poles.** The dry weight of cedar is 20.7 lb. per cu. ft. Green cedar poles weigh approximately 35 to 40 lb. per cu. ft. when cut, and fall to about 25 lb. per cu. ft. in 10 to 18 months of seasoning. Air-dry cedar contains about 20 per cent. of moisture and weighs from 65 to 70 per cent. of the green weight.

The dry weight of chestnut is 28.1 lb. per cu. ft. Green chestnut poles weigh approximately 52 to 56 lb. per cu. ft. when cut, and fall to 40 to 45 lb. per cu. ft. in 8 to 24 months of seasoning. The specific gravity of green chestnut is 0.85 to 0.86.

All things considered, winter-cut poles are the most desirable. They season more regularly and are more immune to decay than those cut in other seasons.

**424. Working unit stresses for wood poles,** adopted by the N. E. L. A.* and the A. E. R. E. A., † are as follows, in lb. per sq. in.

| | | | |
|---|---|---|---|
| Eastern white cedar..... | 600 | Douglas fir..... | 900 |
| Chestnut..... | 850 | White oak..... | 950 |
| Washington cedar..... | 850 | Red cedar..... | 700 |
| Idaho cedar..... | 850 | Bald cypress (heartwood). | 800 |
| Port Orford cedar..... | 1150 | Redwood..... | 650 |
| Long-leaf yellow pine..... | 1000 | Catalpa..... | 500 |
| Short-leaf yellow pine.... | 800 | Juniper..... | 550 |

The above values apply to bending; in compression the above values should be multiplied by the factor $(1-L/60D)$, where $L$ is the length in inches and $D$ is the least side or diameter in inches.

**425. Decay and its prevention.** At ordinary temperatures wood is a very stable compound and unless attacked by living organisms it remains the same for centuries, either in air or under water. Bacteria and fungi are the chief enemies of wood, and they thrive best with warmth and abundance of moisture and air. Contact with the ground results in the most favorable condition for fungus growth; the higher temperatures near the surface of the ground, together with the prevalence of spores, cause decay to start sooner at the surface than 2 or 3 ft. below the surface. Perfect seasoning, together with the use of means of protection against the entrance of moisture, and impregnating compounds (creosote or bichloride of zinc) which prevent fungi from feeding on the wood, are the best means of preservation. The sapwood is more vulnerable than heartwood, but wood cut in the late fall or winter is more durable than that cut in the late spring or summer. The different species, however, differ materially in their resistance to decay. See "Wood Preservation in the U. S.," by W. F. Sherfesee; U. S. Forest Service, Bulletin No. 78; 1909.

**426. Methods of applying preservatives.** The closed-tank method is employed where it is desirable to treat each entire stick or member, such as cross-ties and cross-arms. In the pressure process live steam is first admitted for a time; next this is withdrawn and a vacuum established;

* Report of the Joint Committee on Overhead Line Construction; 1913.
† Report of the Committee on Power Distribution; 1913.

Digitized by Google

finally the preservative is introduced under pressure. This method secures the maximum penetration and absorption.

The open-tank treatment, hot process at atmospheric pressure, is used extensively for treating the butts of poles. The penetration in open-grained porous wood is from 0.75 to 1.00 in., and in dense wood from 0.25 to 0.50 in. The brush treatment secures a penetration ranging from 0.06 to 0.25 in., or from two to three annual rings. The absorption in all cases is increased by seasoning. Also see Bulletin No. 78, U. S. Forest Service, 1909.

**427. Strength of treated timber.** Talbot concluded from his tests of timber (Bulletin No. 41, Eng. Exp. Sta., Univ. of Ill., 1909; also see Forest Service Circular No. 39) that creosoting, under ordinary practice, decreases the strength and the stiffness.

## ROPE AND BELTING

**428. Manila rope.** The weight of Manila rope, based on the tests of the C. W. Hunt Co., is expressed by the formula

$$\text{Wt. per ft.} = 0.34d^2 \quad \text{(lb.)} \qquad (22)$$

where $d$ is the diameter in inches. The tensile strength is given by the formula

$$T = 7{,}160d^2 \quad \text{(lb.)} \qquad (23)$$

where $T$ is the total strength of the rope and $d$ is the diameter in inches. Kirsch concluded from his tests that a rope having a diameter of 1 in. would have an average breaking strength as follows: **Italian hemp**, 9,910 lb.; Hungarian hemp, 9,293 lb.; Manila rope, 7,100 lb.

The Plymouth Cordage Co. gives the following rules for Manila rope: the weight per ft. is equal to the square of the diameter in inches, multiplied by 0.34; the breaking strength is equal to the square of the diameter, multiplied by 7,500; the maximum permissible tension (rope drives) is equal to the square of the diameter, multiplied by 200.

The C. W. Hunt Co. gives factors of safety, for computing the allowable working loads, approximately as follows: tackle, 7; hoisting, 18; transmission, 35. The efficiency of knots in rope ranges from 50 to 90 per cent.

For further data on tests of rope, see "Tests of Metals," reporting Watertown Arsenal tests, Gov. Printing Office, Wash., D. C.

**429. Danger of metal filaments or strands in rope.** Metal filaments are sometimes introduced in ropes to give added strength; when such ropes are used by linemen they become exceedingly dangerous, owing to the probability of communicating electrical shock. Similar danger exists from tape lines made of a fabric base and containing metal threads.

**430. Leather belting** weighs about 60 lb. per cu. ft. and has a tensile strength of from 2,000 to 5,000 lb. per sq. in., or an average of about 650 lb. per in. of width of single belt. See tests of leather belting in Watertown Arsenal Reports ("Tests of Metals") for 1893, Gov. Printing Office, Wash., D. C.

**434. Specific heat of water,** from 0 to 100 deg. cent. (Smithsonian Phys. Tables, 1910).

| Temp. | Sp. ht. | Temp. | Sp. ht. | Temp. | Sp. ht. | Temp. | Sp. ht. |
|---|---|---|---|---|---|---|---|
| 0 | 1.0094 | 20 | 0.9990 | 50 | 0.9980 | 80 | 1.0042 |
| 10 | 1.0023 | 30 | 0.9976 | 60 | 0.9994 | 90 | 1.0070 |
| 15 | 1.0003 | 40 | 0.9974 | 70 | 1.0015 | 100 | 1.0101 |

**435. Atmospheric air*** contains oxygen, nitrogen, carbon dioxide, water vapor and argon. The constituents of pure dry air are as follows:

| | By weight, per cent. | By volume, per cent. |
|---|---|---|
| Nitrogen | 75.50 | 78.06 |
| Oxygen | 23.20 | 21.00 |
| Argon | 1.3 | 0.94 |
| | 100.00 | 100.00 |

Free air contains from 3 to 4 parts of $CO_2$ in 10,000 parts by volume. The standard atmospheric pressure is 29.92 in. (760 mm.) of mercury. The amount of water vapor contained in air depends upon the temperature and the degree of saturation; the ratio of the amount of vapor actually present to that amount required to saturate the air is termed the relative humidity. See "Smithsonian Physical Tables," 5th rev. ed., 1910.

**436. Weight of dry air.** Computed from the formula $w=[1.293052/(1+0.00367t)](h/760)$, the weight of a liter of dry air at 20 deg. cent. and a pressure of 760 mm. of mercury (at 0 deg. cent.) is 1.2046 g.; $t$ is in deg. cent. and $h$ in mm. of mercury at 0 deg. cent. (Bureau of Standards). The following table gives the weight in grams per liter of dry air containing 0.04 per cent. of $CO_2$ (Bur. of Stds.).

| Temp. in deg. cent. | Barometer, in mm. (0 deg. cent., standard gravity) | | | | | |
|---|---|---|---|---|---|---|
| | 720 | 730 | 740 | 750 | 760 | 770 |
| 15 | 1.1611 | 1.1772 | 1.1933 | 1.2095 | 1.2256 | 1.2417 |
| 20 | 1.1412 | 1.1571 | 1.1729 | 1.1888 | 1.2046 | 1.2205 |
| 25 | 1.1220 | 1.1376 | 1.1532 | 1.1688 | 1.1844 | 1.2000 |
| 30 | 1.1035 | 1.1188 | 1.1342 | 1.1495 | 1.1648 | 1.1801 |

**437. The specific heat of air.** Regnault's mean value of the specific heat of air at constant pressure is 0.2375; nitrogen 0.2438; oxygen, 0.2175; hydrogen, 3.409. Taking into account the temperature, the specific heat of air at constant pressure is

$$C = 0.24112 + 0.000009t \qquad (24)$$

where $C$ is expressed in B.t.u. per lb. and $t$ is in deg. fahr.

## MAGNETS

### BY CHARLES R. UNDERHILL

### GENERAL

**1. A magnet** is a body which possesses the property of attracting magnetic substances. All magnets may be divided into two classes, *i.e.*, permanent magnets and electromagnets.

**2. A permanent magnet** is one which retains a nearly constant value of m.m.f. for an indefinite period. The permanent magnets used in practice are made of hardened steel and are magnetised by placing them in a strong magnetic field.

**3. An electromagnet** or temporary magnet is one in which the magnetic field is produced by an electric current. In its simplest form, it consists of a helix of conducting material which, when energised by an electric current, possesses many of the magnetic-field characteristics of a permanent magnet. Since soft iron is capable of being magnetised to a high degree and retains very little permanent magnetism, with the result that the magnetic field may be varied in great degree by regulating the strength of the current, electromagnets are usually provided with soft-iron cores.

### PERMANENT MAGNETS

**4. Permanent magnets are used** where a constant field is desired, as in electrical instruments, magneto-generators, etc. In order to retain its strength, a permanent magnet should have as short an air-gap as possible and the ratio of its length to its cross-sectional area should be great. Unless proper precautions are taken, the steel is likely to crack and warp in hardening.

**5. Permanent magnets lose a portion of their original magnetism** when used for a long time, so that they become what is termed aged. Those used in instruments, magnetos, etc., are **artificially aged** in the process of manufacture. This is accomplished in various ways. One method of aging magnets for watt-hour meters is to pass them several times through a bath of boiling water or oil and then to demagnetise them to about 7 per cent. of the original value by rotating a copper disc between the poles. Another method is to place a large number of magnets parallel to each other, with a copper strip between the poles, and then to demagnetise them by passing a strong current through the strip. (Also see Par. 10.)

**6. Permanent magnets are made from** the best grade of crucible tungsten steel which contains about 5 per cent. of tungsten, a small percentage each of chromium and manganese, and from 0.63 to 0.66 per cent. carbon. Domestic steel of this variety is found to be equal to or better than any imported magnet steel.

**7. Details of manufacture.** The practice of the Sangamo Electric Co. is as follows: After preliminary tests, the steel bars are sheared cold and then heated in a special fuel-oil furnace so arranged that the products of combustion do not come directly in contact with the steel. The pieces are forged at a bright red heat, in a large press, using but one heat if possible. A vertical type press is preferred to the "bull-dozer" type. The pieces are then allowed to cool in the air, if no drilling is required; or, if drilling is necessary, they are packed in mica dust to prevent air-hardening, which takes place to a certain extent even with steel containing no more than

Digitized by Google

5 per cent. of tungsten. The pieces are then ground to dimensions, tumbled to remove all scale, and heated in a fuel-oil furnace, arranged with a recording pyrometer for checking the temperature. The next operation is the hardening or tempering.

**8. The hardening process** is carried on in a darkened room so that the operator can judge the heat, aside from the information obtained from the pyrometer. The pieces are brought to a temperature of 840 deg. to 860 deg. cent., the proper temperature varying according to the carbon content, and are quenched in pure running water at a temperature varying from 40 deg. fahr. in winter, to 70 deg. fahr. in summer. During hardening the pieces are held in special tongs or clamps to prevent springing; they are again tumbled to remove all scale, and then given any final finish grinding that may be required.

**9. Magnetizing process.** The pieces are magnetized by placing them in special jaws which form the pole pieces of a powerful electromagnet, and sufficient current is then switched on, for a brief period, to force the maximum magnetic flux through them.

**10. Artificial aging.** The magnets are artificially aged by placing them in oil and heating to a temperature of 250 deg. fahr. for about one-half hour, after which they are placed on a vibrating or humming device for vibration aging; the latter treatment reduces the strength of the magnet, but not so much as the heat aging. (Also see Par. 5.)

**11. Precautions in handling.** After being japanned, the magnets are tested for field strength and laid away in a tray. In handling, precautions should be taken to prevent undue throwing about after magnetizing and aging; but, unless the magnet has a long air-gap, it is found that no particular care is necessary to prevent further loss in strength. In case a magnet has a long air-gap, as in magneto field magnets, a **keeper** is placed across the poles.

## ELECTROMAGNETS

**12. A continuous-current electromagnet** is one which is designed for operation from continuous-current circuits. In this class, the **effects of inductance** are noticeable only when the magnet is switched in or out of circuit and while it is doing work.

**13. An alternating-current electromagnet** is one which is designed for operation from alternating-current circuits. In this case the magnitude and the direction of the current are varying periodically; hence the effects of inductance are so great as to require the design of the coil and other parts to be radically different from those for continuous-current circuits, although the laws governing the pulls are similar.

**14. Uses.** There are so many uses for electromagnets that it would be a considerable task to enumerate them all, but in most cases their uses are familiar. They are being used in increasing quantities in the electrical control of machines wherein mechanical devices were formerly employed. In general, they may be divided into two classes.

**15. A portative electromagnet** is one designed for holding or lifting only; that is, it is merely intended to grip and hold in place material brought in contact with it.

**16. A tractive electromagnet** is one designed to pull a load through a distance and thus do work.

## TYPES OF ELECTROMAGNETS

**17. A solenoid** is a winding of insulated conductor consisting of a series of superimposed helices of right and left pitch. It is the basis of all of the common forms of electromagnets.

**18. A solenoid-and-plunger** is a solenoid mounted on a suitable non-magnetic bobbin or spool and provided with a movable bar of soft iron or steel called a plunger. When the coil is energized, the plunger becomes magnetized by the influence of the magnetic flux from the current in the coil, and mutual attraction then takes place between the coil and the plunger. If the force of attraction is great enough to overcome the load, the plunger will advance into the coil until their magnetic centers coincide, and thereafter no more work can be done unless the relative positions of the coil and the plunger are again changed by external means.

Digitized by Google

**19. An iron-clad solenoid** is a solenoid-and-plunger provided with an iron or steel frame or jacket. The effect is to confine the magnetic field within the limits of the frame. When provided with a stop, as in Fig. 1, this type is commonly known as a **plunger electromagnet.**

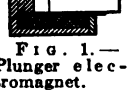

FIG. 1.—Plunger electromagnet.

**20. A bar electromagnet** is a solenoid-and-plunger with the plunger inserted in the solenoid and rigidly fixed in position.

**21. A horseshoe electromagnet** is a bar electromagnet bent into U form in order to bring the pole ends near together. The practical type consists of two bar electromagnets magnetically joined together at one end by means of a **yoke** or **backiron.** Both coils are usually wound in the same direction and their inside wires connected together. The **armature** consists of a piece of soft iron or steel of sufficient length to bridge the gap from pole to pole, and of cross-section great enough to conduct the flux economically.

**22. An iron-clad electromagnet** is a bar electromagnet inserted in a soft-iron or steel cup, so that the rim of the cup and the core of the electromagnet form the attracting surfaces (or poles) for the armature, which usually consists of a disc of soft iron or steel.

**23. Modified types.** There are many modifications of the above fundamental types. For instance, plunger electromagnets are sometimes made in the horseshoe form, and a modification of the horseshoe electromagnet will be recognized in the iron-clad electromagnet. In some telephone relays, an angle-iron is employed instead of the shell or cup.

## GENERAL THEORY OF ELECTROMAGNETS

**24. Maxwell's fundamental equation for the pull** applies strictly to a portative electromagnet consisting of a bar electromagnet separated at its middle and having a hypothetically zero air-gap, so that no flux can leak back from the abutting ends of the half-cores to their opposite ends. The equation for the pull in dynes per sq. cm. is $P = \mathfrak{B}^2/8\pi$. But $\mathfrak{B} = 4\pi\mathfrak{J} + \mathfrak{H}$, wherein $\mathfrak{J}$ is the intensity of magnetization in the iron only. It is convenient to reduce $4\pi\mathfrak{J}$ to $\phi_i/s$, and $\mathfrak{H}$ to $\phi_a/s$, wherein $\phi_i$ is the iron flux, equivalent to the flux in a permanent magnet; $\phi_a$ is the flux in the air-core only, and $s$ is the cross-sectional area of the core in square centimeters. Then

$$\mathfrak{B} = \frac{\phi_i + \phi_a}{s} \qquad \text{(gausses)} \qquad (1)$$

$$\text{whence } P = \frac{\phi_i^2 + 2\phi_i\phi_a + \phi_a^2}{8\pi s^2} \qquad \text{(dynes per sq. cm.)} \qquad (2)$$

**25. Theoretical components of pull.** Conventionally stated, $\phi_i^2/8\pi s^2$ is the purely magnetic pull between the two half-cores; $2\phi_i\phi_a/8\pi S^2$ is the pull due to the "solenoid effect" between the half-coils and the half-cores; and $\phi_a^2/8\pi s^2$ is the pull between the half-coils, which cannot be utilized in practical electromagnets with solidly wound coils. The actual pull, in dynes per square centimeter, for such a portative electromagnet, *i.e.*, when there is no appreciable air-gap between the attracting surfaces of the half-cores, and the coil is solidly wound, is

$$P = \frac{\phi_i^2 + 2\phi_i\phi_a}{8\pi s^2} \qquad \text{(dynes per sq. cm.)} \qquad (3)$$

**26. Total pull between two polar surfaces.** An electromagnet can do work only when there is an air-gap. The longitudinal contraction of the flux in the air-gap of a tractive electromagnet causes the pull. The pull in dynes per square centimeter between the polar surfaces of the cores of a horseshoe electromagnet and its armature, or for any other type of electromagnet with the coils and cores rigidly fixed, relatively, is $P = \phi_g^2/8\pi s^2$, wherein $\phi_g$ is the total average flux producing the pull. This equation expresses the pull in an air-gap, or the pull between two magnetic masses in contact, and holds for permanent magnets.

**27. The pull due to an iron-clad solenoid** or a plunger electromagnet consists of two components, since there are two magnetic circuits in shunt

Digitized by Google

with one another. One of these circuits is through the air-gap, and this pull, in dynes per square centimeter, is equal to $\phi_g^2/8\pi s^2$. The other circuit is the **leakage circuit** from the inner end of the plunger (Fig. 1), through the coil and frame, back to the place where the plunger enters the coil. Hence the pull, in dynes per square centimeter, is

$$P = \frac{\phi_g^2 + 2\phi_l\phi_g}{8\pi s^2} \qquad \text{(dynes per sq. cm.)} \qquad (4)$$

When the air-gap is relatively long, the value of $\phi_l$ is generally greatly in excess of that of $\phi_g$, since the reluctance of the leakage circuit is usually lower than that of the air-gap.

**28. The useful work performed by an electromagnet** is generally defined as initial pull times range or distance of travel. It has been theoretically proven that the **maximum amount of work** may be obtained from an electromagnet when the reluctance of the working air-gap is equal to that of the rest of the magnetic circuit* (Fig. 2). This is true for electromagnets with their coils and cores rigidly fixed, relatively, but is not true for electromagnets with movable plungers, especially when the air-gaps are long and the m.m.fs. are of high value, owing to the "solenoid effect." However, the rule holds for all types of electromagnets so far as the air-gap, only, is concerned. (See Par. 63.)

**29. The maximum work in the air-gap** (initial pull × distance) is obtained when $\mathcal{F}_g\phi_g$, that is, the product of the air-gap m.m.f. and the flux, becomes a maximum. The expression for $\mathcal{F}_g$ is

$$\mathcal{F}_g = \left(\frac{\mathcal{R}_g}{\mathcal{R}_g + \mathcal{R}_i}\right)\mathcal{F}_t \qquad \text{(gilberts)} \qquad (5)$$

wherein $\mathcal{F}_g$ is the air-gap m.m.f., $\mathcal{R}_g$ the reluctance of the working air-gap, $\mathcal{R}_i$ the reluctance of the magnetic circuit exclusive of the working air-gap, and $\mathcal{F}_t$ the total m.m.f. The reluctance of the air-gap is $\mathcal{R}_g = \mathcal{F}_g/\phi_g$. The general theoretical air-gap characteristics are shown in Fig. 2. This is similar to the rule for the maximum wattage which may be obtained in a coil connected in series with a continuous-current line of constant e.m.f. As is well known, the maximum wattage is obtainable when the resistance of the coil is equal to the sum of all of the other resistances in series in the line. Likewise, when the proper length of the air-gap is either increased or diminished, the maximum pull × length of air-gap is diminished.

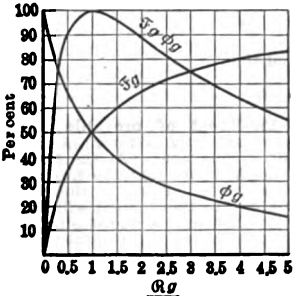

FIG. 2.—Theoretical air-gap characteristics showing conditions for maximum work (pull × distance).

**30. Electrical time-constant.** When quick action is desired, it is necessary that the current reach its maximum value as soon as possible. Referring to Sec. 2, it will be seen that a definite time interval, in each case, is required for the current to reach its maximum value. The relationship between the instantaneous current, the constant impressed e.m.f. and the constants of the circuit is expressed by Helmholtz's law (Sec. 2) thus

$$i = \frac{E}{R}\left(1 - \epsilon^{-\frac{R}{L}t}\right) \qquad \text{(amp.)} \qquad (6)$$

wherein $i$ is the instantaneous value of the current, $E$ the e.m.f. in volts impressed upon the magnet winding, $R$ the resistance in ohms of the winding, $\epsilon$ the base of the Naperian logarithm system ($\epsilon = 2.71828$), $L$ the in-

*Carichoff E. R. "On the Design of Electromagnets for Specific Duty;" *Electrical World*, 1894, Vol. XXIII, pp. 113 and 212.

Digitized by Google

ductance (Par. 31) in henrys, and $t$ the elapsed time in seconds from the moment the circuit was closed. Solving the above equation for $t$,

$$t = -\frac{L}{R} \log_e\left(1 - \frac{R_i}{E}\right) \qquad \text{(sec.)} \qquad (7)$$

wherein $L/R$ is called the time-constant. From this it is seen that for a given ratio of instantaneous current to the Ohm's law or steady current the time-constant is the only factor which determines the time required to establish it. The time-constant is fixed by the magnetic circuit and by the ampere-turns (when iron is present), and is independent of the number of turns, since both the resistance and the inductance vary as the square of the number of turns, for a given winding volume.

**31. The approximate inductance of a magnet,** in which the air-gap is not very long, can be found by assuming the magnet to be connected to a source of alternating e.m.f., of known frequency and having a sine-wave form. Let $l_i$ be the length in cm. of the iron circuit; $l_a$ the length in centimeters of the air-gap; $N$ the number of turns; $s$ the cross-sectional area in square centimeters of the magnetic circuit, and $\phi$ the maximum value of the total flux. Then the alternating e.m.f. which must be impressed upon the winding to produce a maximum flux $\phi$, is

$$E = 4.44 f N \phi 10^{-8} \qquad \text{(volts, effective)} \qquad (8)$$

where $f$ is the frequency in cycles per second. The approximate reluctance is,

$$\mathfrak{R} = \frac{1}{s}\left(\frac{l_i}{\mu} + l_a\right) \qquad \text{(oersteds)} \qquad (9)$$

$\mu$ can be taken from curves in Sec. 4. The m.m.f. is $\mathfrak{F} = 1.257 NI$ wherein $I$ is the effective (root mean square) current in amperes. It follows from $\mathfrak{F} = \phi\mathfrak{R}$ that

$$I = \frac{\phi\mathfrak{R}}{1.257N} \qquad \text{(amp.)} \qquad (10)$$

and then

$$L = \frac{E}{2\pi f I} \qquad \text{(henrys)} \qquad (11)$$

**32. Effect of movable plunger.** Magnets with movable plungers which are designed for quick and powerful action require careful study of the initial conditions. At the first instant, the value of the current increases at such a rate that the flux interlinked with the winding will generate a counter-e.m.f. equal to the impressed e.m.f. The pull produced by the flux due to this current will start the plunger, and the sudden decrease in reluctance due to the closing of the air-gap will produce a corresponding increase in flux and thus decrease the rate of change of the current, that is, the current will be retarded in reaching its final and permanent value. Because of this phenomenon it is usual to design such magnets (for instance, those used on automatic starters) for a much lower impressed e.m.f. than is actually used at the start; in order then to protect the winding, a higher resistance is automatically inserted in series with it at the moment the plunger arrives at the end of its stroke. This resistance limits the current to that value necessary to maintain the required final pull on the plunger.

**33. The action of the plunger in reducing the reluctance of the** magnetic circuit may be approached from the energy standpoint; thus, the total energy which is supplied to the magnetic field up to any instant is

$$W = E\int_0^t i\,dt = \frac{i^2 L}{2} + 0.113 F l \qquad \text{(watt-seconds)} \qquad (12)$$

wherein $i$ is the instantaneous value of the current in amperes, $L$ the instantaneous value of the inductance in henrys, $F$ the average pull on the plunger in pounds, and $l$ the distance traveled in inches.

Digitized by Google

**34. Current-time curves for plunger electromagnets.** Referring to Fig. 3, the current-time curves* for a certain magnet are plotted for different stationary positions of the plunger, each curve representing a given air-gap. If the plunger moves forward before the current has reached its final and permanent value, the reluctance decreases and the current drops

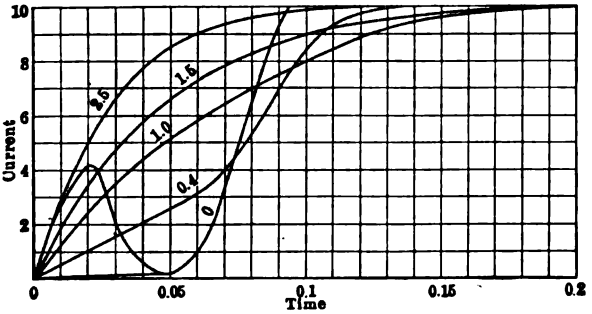

FIG. 3.—Theoretical current-time curves for a plunger electromagnet.

from one curve to the next, corresponding at each instant with the air-gap and the time. If, for instance, after 0.02 sec. the plunger closes the air-gap to 1.5 cm., it is probable that the current will have the same value as though it had increased from zero along the curve corresponding to the air-gap 1.5 cm., and it cannot have a greater value. In Fig. 4, the current-time curves are given for maximum and zero air-gaps; assuming the current to increase along the first curve until *a* is reached, before the pull becomes sufficient to overcome the friction and start the plunger, the latter then moves forward with a rapidly increasing acceleration to the end where the air-gap is zero, and thereafter the current follows the curve corresponding to the zero air-gap to *b*, where the magnetic circuit becomes saturated and the current rises rapidly to the value determined by the resistance of the winding. If an external resistance be inserted by means of a short-circuiting switch actuated by the plunger, the current may be limited to any desired value.

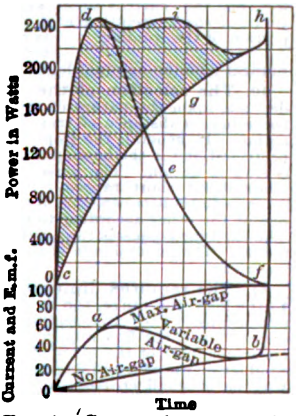

FIG. 4.—Current-time curves for maximum and zero air-gaps.

**35. Energy stored in the magnetic circuit.** The current curves in Fig. 4 can also be chosen to represent the *ir* drop in the winding; then the difference between the final value $I_{max.}$ and the instantaneous value *i*, represents the counter-e.m.f. of inductance, that is, the counter-e.m.f. generated by the flux cutting the turns of the winding. The counter-e.m.f. of inductance multiplied by the current in the winding is the **power supplied to the magnetic circuit.** These power curves are plotted above the current curves in Fig. 4. Curve *cdef* is the power curve for the maximum air-gap; *cghf* is that for zero air-gap, and *cdihf* that for the varying air-gap. The areas under these

*Calculated and plotted by Mr. O. A. Kenyon; 3rd edition, Standard Handbook.

Digitized by Google

curves represent the energy transferred to the magnetic field, in each case. With the moving plunger, the total energy input to the magnetic field is the area *cdihf*, while that left as stored energy at the end of the stroke and which must be dissipated when the circuit is broken is the area *cghf*. The difference between these two, *cdihg* (cross-hatched) represents the energy transformed into mechanical work and dissipated by friction and impact of the plunger during its travel, iron losses being neglected.

**36. Impressed e.m.f.** The final permanent value of impressed e.m.f. in continuous-current magnets is determined by the resistance.

**37. The speed of the magnet action also depends upon the secondary losses** (eddy currents, Sec. 2). These losses tend to reduce the flux in the core and thus retard the attainment of the maximum pull. This effect can be reduced by **laminating** the core and frame and by avoiding the use of a metallic bobbin. It can also be reduced by using fewer turns and larger current.

**38. Slow-speed magnet action** is obtained by increasing the time-constant and the secondary losses. The secondary losses can be greatly increased by dividing the winding into sections and short-circuiting more or less of the sections. Fig. 5 shows the effect of short-circuiting a portion of the winding.* The total number of turns was 8,400; in curve (1), only 2,165 turns were energized, while in curve (2), 2,165 turns were energized and 6,235 turns short-circuited. In the first case it required about 2.5 seconds to reach the maximum current, while in the second case, 4 seconds were required.

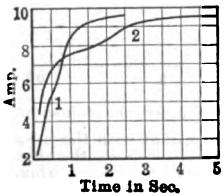

FIG. 5.—Showing the effect on the current-time curve of short-circuiting a portion of the winding.

**39. Inertia of moving system.** When the speed of action is an important factor, the inertia of the load to be moved must be considered. For the same pull and range, a quicker action will be obtained in overcoming the tension of a spring than in moving a mass whose weight is equivalent to the tension of the spring. The total mass to be moved is the sum of that of the plunger and the external load.

**40. The selection of the type of electromagnet for specific work** depends upon the nature of the e.m.f. (whether continuous or alternating) the range or distance of travel, and the rate of travel or the quickness of action. In general, the iron-clad solenoid type is mechanically the better protected and is the best adapted for a long range and a strong pull, but it is slow in action. The horseshoe type has the quicker action, but is only adapted for short ranges. The plunger-electromagnet type has an action intermediate between the above-mentioned types and may approximate one or the other according to the range and the dimensions of the plunger. The bar type possesses the quickest action of all, but its pull is comparatively feeble. The general rule is that what is lost in time is gained in pull and *vice versa*.

**41. The required dimensions of an electromagnet** are proportional to the load, the range, the duration of excitation and the interval between excitations. The cross-sections of the plungers, cores and frames will depend upon the flux required to produce the desired pull. In long-range electromagnets of the solenoid type, wherein the pull is proportional to the product of the magnetizing force times the flux in the plunger, the plunger may be of small cross-section, if the duration of excitation is to be brief, since the magnetizing force of a comparatively small coil may be made great for a short period without danger of injury from overheating. This does not hold for a horseshoe type, since the main pull is dependent upon the flux which the cores are able to conduct, and is only slightly affected by an increase in the magnetizing force after the cores approach saturation.

**42. Electromagnets designed for continuous service** must have windings of such volume and radiating surface, and wires of such cross-sections,

* Lindquist, D. L. "Alternating-current Magnets;" *Electrical World*, 1906, Vol. XLVII, p. 1295.

Digitized by Google

that the coils will not become overheated, but the proper pull will be maintained even after the winding has been in circuit continuously for many hours. The designer should allow too much space, rather than too little, for the winding and the insulation of the coil, because, while the coil may be relatively small for intermittent service, it is often found necessary or desirable to leave the coil in circuit longer than originally intended.

**43. The air-gap pull** of any electromagnet is

$$F' = \frac{\mathfrak{B}'^2 s'}{72{,}130{,}000} \quad \text{(lb.)} \qquad (13)$$

or

$$F = \frac{\mathfrak{B}^2 s}{8\pi \times 981{,}000} \quad \text{(kg.)} \qquad (14)$$

where $\mathfrak{B}'$ and $\mathfrak{B}$ are the flux densities in maxwells per square inch and per square centimeter respectively; $s'$ and $s$ are the cross-sectional area of the core or plunger in square inches and square centimeters respectively.

**44. Curves plotted between the pull per unit area of core and the flux density** are shown in Fig. 6. The pull is plotted with maxwells per square centimeter, but maxwells per square centimeter are also plotted with maxwells per square inch so that pull can be read off for either one.

**45. Relation between pull and air-gap.** In designing magnets, an approximate idea of the

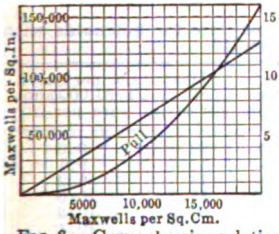

FIG. 6.—Curve showing relationship between the pull per unit area of core and the flux density.

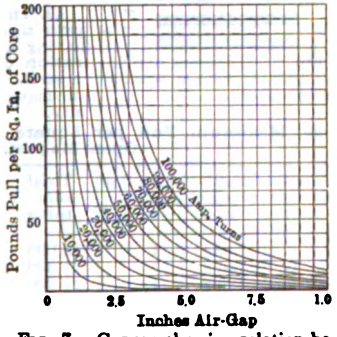

FIG. 7.—Curves showing relation between the pull in lb. per sq. in. and the air-gap for different amp-turns.

principal dimensions and proportions can be found from the curves given in Fig. 7, which show the relation between the pull in pounds per square inch and the air-gap for different numbers of ampere-turns.

## CONTINUOUS-CURRENT TRACTIVE ELECTROMAGNETS FOR LONG RANGE

**46. Solenoids** with plungers only, *i.e.*, without an iron frame, are seldom used in practice except in cases where it is desired to take advantage of the peculiar pull characteristics. However, it is important to understand their actions since the design of all movable-core electromagnets is influenced by the characteristics of the simple coil-and-plunger.

**47. The magnetizing force of a solenoid** is a maximum at its centre, falling off to about one-half of the maximum at each end of the winding. When one end of the plunger is placed in or near the end of the solenoid it becomes magnetized, and mutual attraction results between the flux in the plunger and the magnetizing force due to the ampere-turns in the winding of the solenoid. The plunger becomes more and more saturated as it enters the solenoid, and, in case the plunger is not much longer than the solenoid, all tractive effort ceases when the respective magnetic centres of the solenoid and the plunger coincide. As a result, the maximum pull always occurs after the inserted end of the plunger has passed the middle of the solenoid, although, in cases of long solenoids and where the magnetis-

Digitized by Google

ing force has a high value as compared with the cross-sectional area of the plunger, the maximum pull may occur for a considerable distance on each side of the middle of the solenoid. On the other hand, with very short solenoids, the maximum pull may occur at or near the end of the solenoid opposite to that at which the plunger enters.

**48. Characteristic pull with solenoid and plunger.** Fig. 8 shows the approximate pull diagram for different positions of the plunger. The expression for the maximum uniform pull is

$$F = Cs\frac{NI}{l} \qquad \text{(lb.)} \qquad (15)$$

where $I$ is the current in amp., $N$ the number of turns, $s$ the cross-sectional area of the core or plunger in square inches, $l$ the length of the solenoid in inches and $C$ the pull in pound per square inch per ampere-turn per inch. $C$ depends upon the proportions of the coil, the degree of saturation, and the length, physical character and chemical purity of the plunger. Par. 50 gives values for $C$ for various solenoids tested by the author.

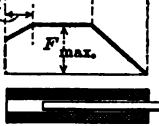

FIG. 8.—Diagram of plunger pull for simple solenoid and plunger.

**49. In magnets with long air-gaps,** the path through the iron can be considered as having no reluctance. Therefore the **saturation characteristic** can be assumed to be a straight line, and the ampere-turns for the air-gap directly proportional to the flux density.

**50. Maximum Pull per Square Inch of Core for Solenoids with Open Magnetic Circuit***

| Length of coil (in.) | Length of plunger (in.) | Area of core (sq. in.) | Total amp-turns | Amp-turns per in. | Max. pull, lb. per sq. in | Lb. per sq. in. per 1,000 amp-turn per in. |
|---|---|---|---|---|---|---|
| 6 | Long | 1 | 15,000 | 2,500 | 22.4 | 9.0 |
| 9 | Long | 1 | 11,330 | 1,260 | 11.5 | 9.1 |
| 9 | Long | 1 | 14,200 | 1,580 | 14.6 | 9.2 |
| 10 | 10 | 2.76 | 40,000 | 4,000 | 40.2 | 10.0 |
| 10 | 10 | 2.76 | 60,000 | 6,000 | 61.6 | 10.3 |
| 10 | 10 | 2.76 | 80,000 | 8,000 | 80.8 | 10.1 |
| 12 | Long | 1 | 11,200 | 930 | 8.75 | 9.4 |
| 12 | Long | 1 | 20,500 | 1,710 | 16.75 | 9.8 |
| 18 | 36 | 1 | 18,200 | 1,010 | 9.8 | 9.7 |
| 18 | 36 | 1 | 41,000 | 2,280 | 22.5 | 9.8 |
| 18 | 18 | 1 | 18,200 | 1,010 | 9.8 | 9.7 |
| 18 | 18 | 1 | 41,000 | 2,280 | 22.5 | 9.8 |

NOTE.—These tests indicate that nothing is gained in maximum pull by making the plunger considerably longer than the coil.

**51. The diameter of the coil** should be about three times that of the plunger, and the **length of the coil** should be at least two or three times its outside diameter whenever possible.

**52. The range** is directly proportional to the length of the coil, regardless of the ampere-turns.

**53. The pull in an iron-clad solenoid,** with or without a stop, is composed of two components; one is the pull between the end of the stop or frame and the plunger, and the other is that between the winding and the plunger. The latter is all important at the beginning of the stroke, but near the end the stop-pull becomes predominant. The expression for the pull is

$$F = s\left(\frac{NI}{l_{sc}}\right)^2 + \frac{sCNI}{l} = sNI\left[\frac{NI}{l_{sc}^2} + \frac{C}{l}\right] \qquad \text{(lb.)} \qquad (16)$$

* Underhill, C. R. "The Practical Design of the Solenoid;" *Electrical World and Engineer*, 1905, Vol. XLV, p. 796.

Digitized by Google

where $s$ is the cross-sectional area of the core in square inches, $I$ the current in amp., $N$ the number of turns, $l_a$ the length of the air gap in inches, $l$ the length of the coil in inches, and $c$ and $C$ constants, which depend on the proportions of the magnet, the materials used and the degree of saturation. Approximate values for ordinary soft-iron cores are $c = 2{,}600$; for lengths of coil greater than 10 times the diameter of the plunger, $C = 0.0096$ (see Par. **50** for values of 1,000 $C$).

**54. Formula for pull characteristic.** Referring to the pull diagram (Fig. 8), it will be seen that the solenoid pull is assumed to decrease as a straight-line function, commencing at a point about $0.4l$ from the end of the coil.* From this point on the total pull due to the plunger electromagnet can be expressed thus:

$$F = sNI\left[\frac{NI}{l_a{}^2c^2} + \frac{l'c}{0.4l^2}\right] \qquad \text{(lb.)} \qquad (17)$$

wherein $l'$ is the distance in inches which the plunger is inserted in the coil. The constants are the same as those given in Par. **53**.

**55. Test data on pull characteristics.** Fig. 9 shows curves from actual test.* Curve (1) is that of a simple coil-and-plunger; (2) that of a coil-and-plunger with stop; (3), that of an iron-clad coil-and-plunger; (4) and (5) show the same iron-clad coil with different lengths of stop. All these curves were made with the same coil, which was 12 in. long and had a total of 10,000 amp-turns, or 834 amp-turns per linear inch.

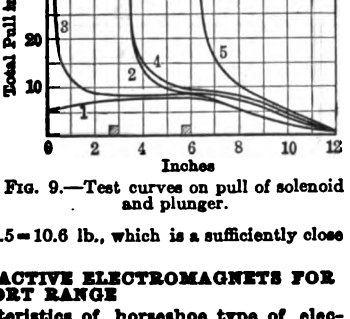

FIG. 9.—Test curves on pull of solenoid and plunger.

**56. Analysis of test data** (Par. **55**). Referring to Fig. 9, the pull with the iron-clad magnet, curve (4), corresponding to the position 5 ($l_a = 2$ in.) of the plunger, is 10.75 lb., approximately. Referring to Par. **49**, the pull due to the coil alone is about 9.7 lb. per square inch, per 1,000 amp-turns per inch, or $9.7 \times 0.834 = 8.1$ lb. Next referring to Fig. 7, it is found that corresponding to $l_a = 2$ in., and 10,000 amp-turns, the pull is about 2.5 lb. per square inch; adding $8.1 + 2.5 = 10.6$ lb., which is a sufficiently close check for all practical purposes.

## CONTINUOUS-CURRENT TRACTIVE ELECTROMAGNETS FOR SHORT RANGE

**57. Test data on pull characteristics of horseshoe type of electromagnet.** Fig. 10 shows the test characteristics of the horseshoe electromagnet in Fig. 11.† These curves should be compared with those in Fig. 7.

**58. Test data on pull characteristics of clapper type of electromagnet.** One of the modifications of a horseshoe electromagnet is the clapper type shown in Fig. 12. Fig. 13 shows the test characteristics of this magnet, as determined by the Cutler-Hammer Mfg. Co. The cylindrical surface of this magnet is approximately 25 sq. in.

**59. Electromagnets used in railway signal apparatus** must respond to very slight changes in current strength. For instance, a 4-ohm **track relay**, operating on an e.m.f. of 1 volt, must attract its armature with sufficient force to close four contacts with a current of 75 milliamp. and the armature must drop away when the current passing through the coils is reduced to 40 milliamp. A minimum air-gap of $\frac{1}{64}$ in. is maintained between the poles of the magnet and the armature, by means of stop pins of non-

* Underhill, C. R. "The Law of the Plunger Electromagnet;" *Electrical World and Engineer*, 1905, Vol. XLV, p. 934.

Digitized by Google

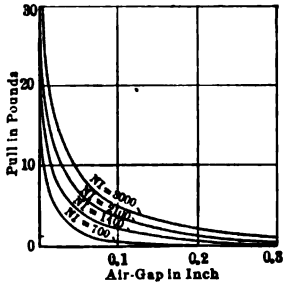

FIG. 10.—Test curves on pull of horseshoe electromagnet.

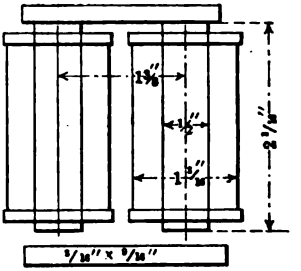

FIG. 11.—Horseshoe type of electromagnet.

magnetic material located in the armature directly under the centre of the magnet cores. The total amp-turns, with 0.075 amp., are 127.5; the cores are ⅜ in. in diameter, and each spool is 4 in. long by 2 in. in diameter. In general, signal relays are required to release their armatures when the energising current is reduced one-half.

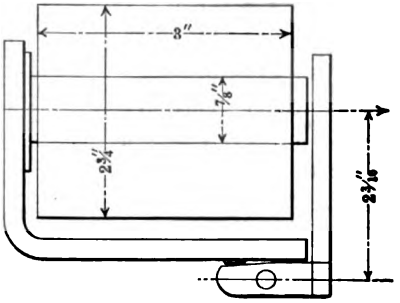

FIG. 12.—Clapper type of horseshoe electromagnet.

**60. Electromagnets for telegraph and telephone service,** like those for signal apparatus, are designed to perform the sole function of closing or opening one or more local contacts which control other circuits and apparatus. The armatures of these magnets customarily work through very limited ranges, not exceeding as a rule a very small fraction of an inch; the opposing force is sometimes gravity, sometimes a light spring. Such relays are also wound differentially for certain kinds of work, and sometimes are polarized (having a permanently magnetised steel core) in order to respond only to currents flowing in a given predetermined direction around the windings (see Sec. 21).

**61. The equation for the pull due to electromagnets of the horseshoe type** is given by

$$F = s\left(\frac{NI}{l_{ac}}\right)^2 \qquad \text{(lb.)} \qquad (18)$$

where the constants are the same as those given in Par. 53. The total length of all the air-gaps is to be taken for $l_a$. The equation is only approximately correct, in this case, owing to leakage. It is better to increase the

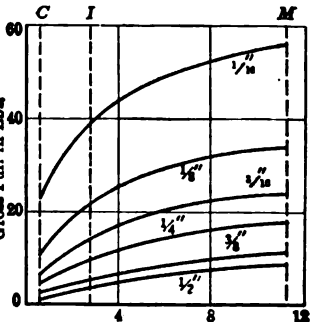

FIG. 13.—Test curves on pull of clapper type of electromagnet.

Digitized by Google

ampere-turns about 50 per cent. to allow for leakage, depending upon the length of the air-gaps.

## CONDITIONS FOR MAXIMUM WORK

**62. The work in the air-gap (pull × distance) of a magnet becomes a maximum** when the air-gap reluctance is equal to that of the rest of the circuit (Par. 29). In Fig. 14, $F_s$ is the solenoid pull, $F_g$ is the air-gap pull, and $F_t$ is the total pull as ascertained by actual test* of a plunger electromag-

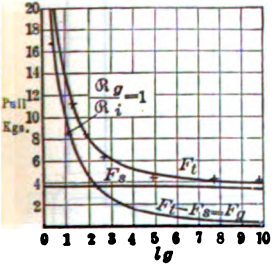

FIG. 14.—Components of pull with a plunger electromagnet.

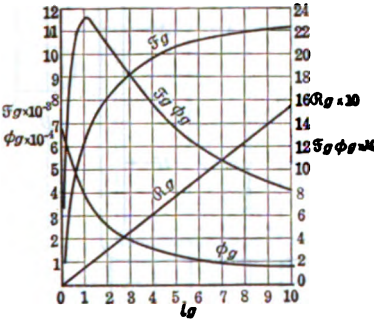

FIG. 15.—Calculated air-gap characteristics of a plunger electromagnet.

net. Fig. 15 shows the calculated air-gap characteristics which should be compared with those in Fig. 2 (Par. 29); $l_g$ represents the length of air-gaps in centimeters. The actual work obtained in the air-gap, the work due to the coil-and-plunger, and the total work are represented by curves $W_g$, $W_s$, and $W_t$, respectively, in Fig. 16. It is evident that the work (pull × distance) due to a solenoid-and-plunger, or plunger electromagnet, of the character of that tested, is limited only by the length of stroke. When the solenoid pull is very weak as compared with the air-gap pull, the maximum work will fall between these two extremes. In general, electromagnets are designed for maximum initial pull × distance or length of stroke. Exceptions are lifting magnets and those used in electric hammers. The amount of material used to construct an electromagnet depends either upon the time it will receive electric energy after it has performed its work, the frequency at which it performs its work, or both.

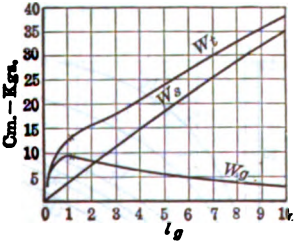

FIG. 16.—Components of work (pull × distance) performed by a plunger electromagnet.

## STANDARD ELECTROMAGNETS

**63. Data on standard electromagnets.** The following figures, tables, and charts show the dimensions and characteristics of some standard electromagnets (The Cutler-Hammer Mfg. Co.). The curves in general represent tests with 115-volt direct-current coils. Three classes of duty are listed (see Figs. 17 to 31, inclusive).

**69. Two forms of plungers** are shown; one is conical, and the other square at the ends. The curves show the former to be preferable on most of the long-stroke types, as the tendency is to increase the starting pull and reduce the final pull. For short strokes, the square-end type is preferable.

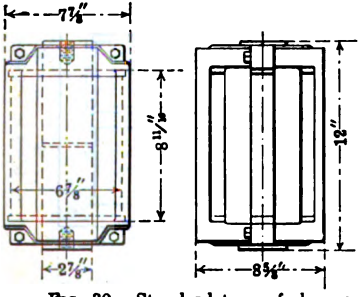

FIG. 30.—Standard type of plunger electromagnet with flat-end plunger. (See Fig. 31.)

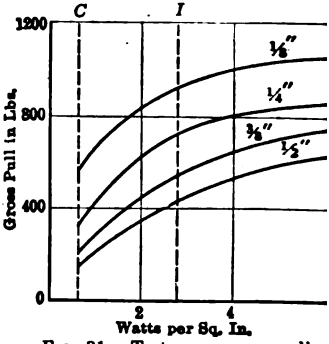

FIG. 31.—Test curves on pull of standard type plunger electromagnet in Fig. 30.

## PORTATIVE ELECTROMAGNETS

**70. Lifting magnets.** Large iron-clad magnets called lifting magnets are now extensively used for the handling of materials in all branches of the iron and steel industry. They are used for handling pig iron, scrap, castings, billets, tubes, rails, plates and crop ends; for loading and unloading cars and ore vessels, and for handling skull-cracker balls and miscellaneous material.

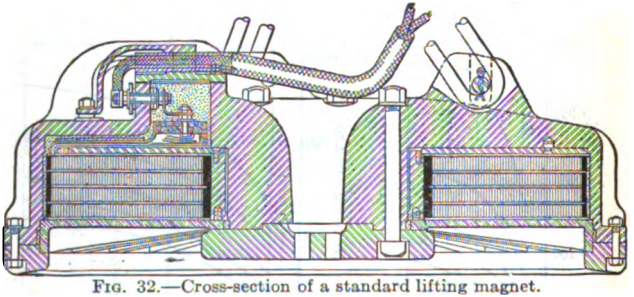

FIG. 32.—Cross-section of a standard lifting magnet.

**71. Operation.** All lifting magnets, of whatever make, are suitable for use on continuous-current circuits only. It is not customary to operate the magnets on very high voltages, owing to the difficulty of securing insulating material that will withstand the high inductive reaction that occurs when the circuit of a magnet is suddenly opened. Standard magnets are designed for operation on 220-volt continuous-current circuits.

**72. Lifting load.** It is quite impossible to calculate the load which may be lifted, owing to the varying contact of the load, but Par. **73**, giving a table published by one of the leading manufacturers, shows the approximate lifts for various magnets and materials.

Digitized by Google

## 73. Dimensions, Energy Requirements and Capacities of Lifting Magnets

| Magnet size | Net weight, lb. | Continuous-current energy requirements | Approximate lifting capacity in lb. | Dimensions; three-point chain suspension | | Adaptation |
|---|---|---|---|---|---|---|
| | | | | Head room required | Outside diameter of magnet | |
| 18 in. | 350 | 1.8 amp. at 220 volts | ..... | 12 in. | 19½ in. | Handling light finished parts, also light iron or steel castings. A pair of these magnets will handle pipe up to 2-in. diameter, economically. |
| 24 in. | 750 | 5 amp. at 220 volts | ..... | 23 in. | 24 in. | Similar to the 18 in. Can also handle skull-cracker balls up to 8,000 lb. |
| 36 in. | 1,800 | 17.5 amp. at 220 volts | 800 to 1,000 | 42 in. | 36 in. | For general service in handling pig iron, scrap, etc., where a large capacity is not required. Sometimes used with locomotive cranes. |
| 43 in. | 3,300 | 30 amp. at 220 volts | 1,300 to 1,500 | 45 in. | 43¾ in. | Primarily designed for use with locomotive cranes. Handles a fair average load and yet is not a heavy magnet and does not take so much energy as to cause an undue drain on the crane boiler which must supply the magnet engine-generator set. |
| 52 in. | 5,200 | 40 amp. at 220 volts | 1,800 to 2,000 | 50 in. | 52 in. | For general work. Used extensively in open-hearth steel plants for handling stock. |
| 62 in. | 7,500 | 55 amp. at 220 volts | 2,400 to 2,800 | 56 in. | 62½ in. | Used where a large tonnage must be handled. Designed as the largest magnet which can be used satisfactorily with a 5-ton crane. |

With large single pieces such as castings, skull-cracker balls, etc., the lifting capacity is many times greater, becoming for example 60,000 lb. in the case of the 62-in. magnet.

Digitized by Google

**74. General construction.** These magnets are very rugged in construction, as they are subject to exceedingly rough usage. The frame or body of the magnet is made, in one instance, of a special grade of dynamo steel which combines great strength and ductility with excellent magnetic qualities. They are designed to withstand heat without injury and are waterproof. Fig. 32 shows the construction of a lifting magnet made by the Cutler-Hammer Clutch Co.

**75. Operating cost.** The Cambria Steel Co. state that their costs for unloading material from broad-gage cars into open-hearth charging boxes are as follows: Handling light scrap, 3.15 cents per ton; handling heavy scrap, 2.28 cents per ton; handling pig iron, 3.06 cents per ton. These costs include: electric energy, repairs, interest and depreciation for crane and magnet, and all labor. About 50 per cent. of the foregoing cost is for labor in trimming the charging boxes.

The Inland Steel Co. reports that about 4,000,000 lb. of machine cast pig iron were unloaded in 10.5 hr. by two 62-in. magnets. The average lift per magnet was 3,427 lb.

**76. Holding magnets.** Portative magnets are extensively used for holding tools and materials in grinding and other machines. The no-load release magnet belongs to this class.

## ALTERNATING-CURRENT TRACTIVE ELECTROMAGNETS

**77. The design of an alternating-current magnet** involves calculations which are essentially the same as those for an ordinary transformer. The total flux is determined by the number of turns, the supply voltage and the frequency; thus

$$E = \frac{2\pi f N \phi_{max}}{\sqrt{2}\,10^8} = 4.44 N \phi_{max}\,10^{-8} \text{ (volts, effective)} \quad (19)$$

and

$$\phi_{max} = \frac{E\,10^8}{4.44 f N} \quad \text{(maxwells)} \quad (20)$$

where $f$ is the frequency in cycles per second, $N$ the number of turns, and $E$ the impressed e.m.f. in volts.

Taking $f$ and $N$ as constant,

$$\phi_{max} = s\mathfrak{B}_{max} = KE \quad \text{(maxwells)} \quad (21)$$

and

$$\mathfrak{B}_{max} = K\frac{E}{s} \quad \text{(gausses)} \quad (22)$$

That is, for a given impressed e.m.f. the flux density will vary inversely as the area of the core.

**78. Flux density.** Since the air-gap pull varies approximately as the square of the flux density, it would appear that the flux density should be as great as possible. However, the iron losses also increase with the flux density, so that the maximum possible flux density is not the most efficient.

**79. Iron losses.** The major portion of the total loss takes place in the iron rather than in the copper. The **hysteresis loss** (Sec. 2) is calculated in the same way as that of a transformer, and denoted by $P_h$. The **eddy-current loss** (Sec. 2) is denoted by $P_e$. Then the total core loss is

$$P_c = P_h + P_e \quad \text{(watts)} \quad (23)$$

**80. The quadrature exciting watts** are expressed thus:

$$P_x = 2.5 f \frac{\phi^2_{max}}{s}\left(l_a + \frac{l_i}{\mu}\right)10^{-8} \quad \text{(watts)} \quad (24)$$

wherein $l_a$ is the length of the air-gap in centimeters, $l_i$ the mean length in centimeters of the magnetic circuit in the iron, and $s$ is the cross-sectional area of the core in square centimeters. Expressing this in terms of the volume of the air-gap and of the iron, which quantities must be known in determining the core losses,

$$P_x = 2.5 f \mathfrak{B}^2_{max}\left(V_a + \frac{V_i}{\mu}\right)10^{-8} \quad \text{(watts)} \quad (25)$$

Digitized by Google

wherein $V_a$ and $V_i$ are the volumes in cubic centimeters of the air-gap and the iron, respectively. Values of permeability may be found in Sec. 4.

**81. The total exciting current** may be found as follows: The wattless or magnetizing component is

$$I_x = \frac{P_x}{E} \qquad \text{(amp.)} \qquad (26)$$

The energy component, assuming $I^2R$ losses in the winding to be negligible, is

$$I_r = \frac{P_h + P_e}{E} \qquad \text{(amp.)} \qquad (27)$$

and the total exciting current is

$$I = \sqrt{I_r^2 + I_x^2} \qquad \text{(amp.)} \qquad (28)$$

The copper loss in the winding is

$$P_c = I^2R \qquad \text{(watts)} \qquad (29)$$

Adding this to the core loss, we have approximately for the total loss

$$P = P_h + P_e + P_c \text{ (watts)} \qquad \text{(watts)} \qquad (30)$$

Then the energy component of the exciting current is

$$I'_r = \frac{P}{E} \qquad \text{(amp.)} \qquad (31)$$

and the total exciting current is

$$I' = \sqrt{I'^2_r + I_x^2} \qquad \text{(amp.)} \qquad (32)$$

which is approximately correct. This current can be used to find a new copper loss, and the calculations can be repeated as far as it is thought worth while.

**82. Effect of temperature on iron losses.** The losses in the core decrease with a rise in temperature, and since the core losses form the major portion of the total losses, the efficiency will increase with a rise in temperature.

**83. Lamination of magnetic circuit.** The magnetic circuit should naturally be laminated; this may be done in a way similar to that used in transformer construction; or the core can be made solid, and slots $\frac{1}{32}$ in. wide and $\frac{1}{4}$ in. or more in depth milled lengthwise in it. The magnetic circuit can also be constructed by winding iron ribbon spirally about a spider.

**84. Pulsation of pull.** In single-phase magnets the pull varies from zero to a maximum, and back, twice during each cycle. This causes a vibration of the plunger against the stop and gives rise to a considerable noise. The latter may be largely overcome by means of a **shading coil**, the invention of Mr. D. L. Lindquist, which consists of a ring of solid metal set into the end of the plunger or the stop; this splits the phase so that flux is always present in the sealed air-gap, and the pull is never zero.

**85. Air-gap pull.** If there was no reluctance excepting in the air gap and also if there were no iron losses, the mean effective air-gap pull* would be constant regardless of the length of the air gap. In practical electromagnets, the presence of reluctance and iron losses prevents the current from falling to zero when the air gap closes, so that, for a very short air gap, the pull characteristics are somewhat similar to those for continuous-current electromagnets.

**86. Calculation of pull.** For a given number of effective ampere-turns, the laws stating the pull with alternating-current electromagnets are identical with those for continuous-current electromagnets (barring core losses); but, since the current is reduced as the reluctance of the air-gap is reduced, during the travel of the armature or plunger, the characteristics of alternating-current electromagnets are different from those for continuous-current electromagnets. However, the true pull may be determined, for any length of air-gap, by calculating the effective ampere-turns for all lengths of air-gap and then calculating the pulls with the ampere-turns so deduced, by the equations given in Par. **53**.

## POLYPHASE ELECTROMAGNETS

**87. Test data on two-phase electromagnet.** Fig. 33 shows the relation between volt-amperes and pounds pull for a two-phase magnet designed and tested by D. L. Lindquist.* The magnet contained four coils, each wound with 220 turns of No. 14 A.W.G. copper wire, the cross-sectional area of the core being 1.94 sq. in. The test was made with the magnet-winding connected to a two-phase 60-cycle system. The method of connecting the coils is shown in Fig. 34.

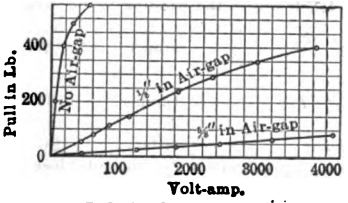

FIG. 33.—Relation between volt-amp. and pull for a two-phase electromagnet.

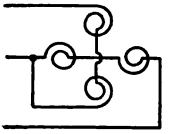

FIG. 34.—Connections of two-phase electromagnet.

**88. Pulsation of pull.** Theoretically, the pull in magnets equipped with polyphase windings should be constant and equal to the maximum pull due to the maximum flux produced in one phase. This, however, is only true when the e.m.f. wave is a pure sine-function. Distortion of the e.m.f. wave will alter the mean effective pull. In any case, if the load exceeds the minimum instantaneous pull, there will be chattering exactly similar to that in a single-phase magnet.

**89. Polyphase magnets used in signal relays** are, in effect, induction motors so designed that the rotor can revolve through a sufficient angle to operate the contacts. This gives a constant drag on the rotor due to the rotary magnetic field and avoids chattering.

## HEATING OF ELECTROMAGNETS

**90. Capacity limited by heating.** The capacity of a given electromagnet is limited by the amount of heat which it can dissipate per unit time without exceeding a given or safe temperature rise.

**91. The temperature rise** can be measured by placing a thermometer against the outside surface or by measuring the change in resistance (Sec. 3). The general formula given below supposes the mean temperature rise to be measured by the thermometer method. The resistance method gives results which are from 1.5 to 2 times greater than those obtained with a thermometer, depending upon the depth of the winding, circulation of the air, etc.

**92. Formula for temperature rise.** The general equation for the final temperature rise in a given coil is

$$t_e = k\frac{P}{A} \qquad \text{(deg. cent.)} \qquad (33)$$

where $P$ is the power, in watts, dissipated in the coil; $A$ the outside cylindrical surface of the coil (the ends are counted only in short coils, and the inside surface is not counted), and $k$ is the temperature rise in centigrade degrees per watt per square inch of outside cylindrical surface. Values for the constant, $k$, in the above formula differ widely according to the proportions of the coil, the depth of the winding, etc. The following values represent average practice. For open electromagnets, $k = 130$; for iron-clad electromagnets, $k = 95$.

**93. Safe temperature limits.** The final temperature rise varies between 50 deg. cent. and 75 deg. cent. according to the specifications, the climate, the depth of winding, etc. The internal temperature rise is limited to that which

* Lindquist, D. L. "Polyphase Magnets;" *Electrical World*, 1906, Vol. XLVIII, p. 128. "Characteristic Performance of Polyphase Magnets," *Electrical World*, 1906, Vol. XLVIII, p. 564.

Digitized by Google

the insulation can successfully withstand. The temperature inside the coil must necessarily be higher than that on the outside.

**94. The watts per square inch** for a series of standard magnets are given in Par. 68. These values may be used for magnets within the range of proportions shown in Fig. 17, Fig. 20, Fig. 27 and Fig. 30.

**95. Hot resistance.** The approximate final resistance of a coil which has been in circuit for a sufficient length of time to become thoroughly heated is

$$R_t = R_s(1 + \alpha_{t_s} t) \quad \text{(ohms)} \quad (34)$$

where $R_s$ is the resistance of the coil at room temperature; $R_t$ the final resistance; $t$, the rise in temperature in deg. cent. above room temperature; and $\alpha_{t_s}$ is the mass resistance temperature coefficient at room temperature (see Sec. 4). The standard room temperature is 25 deg. cent. Roughly, it may be assumed that the resistance of copper will be increased 1 per cent. for each 2.5 deg. cent. rise in temperature, or for each 5 deg. fahr.

**96. Coils impregnated** with high-melting and good heat-conducting compounds are able to withstand more applied power than untreated coils. In alternating-current magnets, the ferric parts also become heated (see Par. 73).

## MAGNET WIRES

**97. Wire insulation.** Wires commonly used in the winding of electromagnets are insulated with enamel, silk or cotton; or combinations of enamel and cotton, or enamel and silk.

**98. Table of Diameters of Magnet Wires**

**99. Space factor.** The most efficient winding is that which contains the maximum amount of conducting material; hence a thin insulation of high dielectric strength is desirable. The space factor or **activity coefficient** is the ratio of the space occupied by the insulated conductor to that occupied by the bare conductor. This is conveniently expressed in terms of turns per square inch. The Tables (Par. **98, 102, 104, 106**) show the relative values for the various wires. Enamel and silk, and enamel and cotton, are designed to replace double-silk- and double-cotton-covered wires, respectively; the former two have higher activity coefficients and greater dielectric strengths than the latter two.

## WINDING CALCULATIONS

**100. Winding formulas.** In what follows let

$d$ = diameter of bare copper wire in inch,
$R_l$ = ohms per linear inch,
$d_l$ = diameter of insulated wire in inch,
$t''$ = turns per linear inch,
$n''$ = layers per inch,
$N_s$ = turns per square inch,
$R_v$ = ohms per cubic inch.

Then the number of **ohms per linear inch** is

$$R_l = 8{,}628 d^{-2} 10^{-10} \tag{35}$$

and

$$t'' = d_l^{-1} \text{ (or is found by actual count)} \tag{36}$$

For layer windings with no paper between layers,

$$n'' = t'' \text{ (approx.)} \tag{37}$$

When paper is used,

$$n'' = (d_l + t_p)^{-1} \tag{38}$$

wherein $t_p$ is the thickness of the paper layer.

The **turns per square inch** and the **ohms per cubic inch** are given by

$$N_s = t'' n'' \tag{39}$$

$$R_v = N_s R_l \tag{40}$$

The properties and dimensions of bare copper wires will be found in Sec. 4. Furthermore let

$T$ = thickness of wall of winding in inches,
$L$ = actual length of winding in inches,
$p_a$ = average perimeter or mean length of turn in inches,
$S$ = longitudinal cross-sectional area of winding in square inches,
$V$ = volume of winding in cubic inches.

The **winding cross-section** and the **winding volume** are

$$S = TL \tag{41}$$

$$V = S p_a \tag{42}$$

In all usual shapes of coils, the **thickness of coil-wall** is $T = n/n''$, where $n$ is the number of layers. For coils wound on cores or forms of the shapes in Fig. 35, the equation

$$p_a = 2(a + b + 1.571T - 0.859r) \tag{43}$$

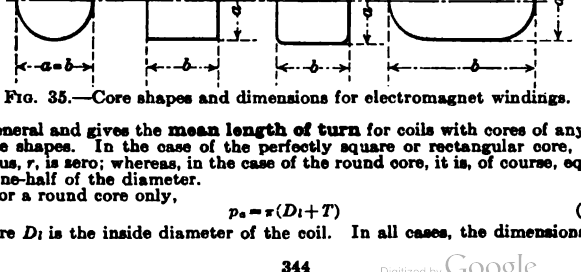

FIG. 35.—Core shapes and dimensions for electromagnet windings.

is general and gives the **mean length of turn** for coils with cores of any of these shapes. In the case of the perfectly square or rectangular core, the radius, $r$, is zero; whereas, in the case of the round core, it is, of course, equal to one-half of the diameter.

For a round core only,

$$p_a = \pi(D_l + T) \tag{44}$$

where $D_l$ is the inside diameter of the coil. In all cases, the dimensions of

Digitized by Google

the insulated cores are assumed, so far as the inside dimensions of the winding are concerned.

The **total number of turns** in a winding is given by

$$N = TLN_a \text{ or } N = n''t''TL \tag{45}$$

The **resistance** of a winding is expressed by

$$R = VR_v \text{ or } R = p_a NR_l \tag{46}$$

**101. Formula for ampere-turns.** The calculations of windings for electromagnets are generally controlled by the ampere-turns to be developed and the energy loss in watts which can be safely allowed. This reduces to the problem of finding the size and kind of insulated wire which will give the proper proportions of turns and resistance. For continuous-current electromagnets, the equation for the ampere-turns for a given e.m.f. is

$$NI = \frac{E}{p_a R_l} \tag{47}$$

Conversely, the size of wire is found from the table opposite the nearest value for $R_l = E/NIp_a$. For the proper dimensions of a coil to radiate a given amount of heat see Par. **92**.

| 38 | ..... | ..... | 27,800 | 23,700 | 49,300 |

**103. Final calculations.** Having found the proper size of wire, it is customary to make preliminary calculations for turns, resistance, etc., and

Digitized by Google

then to make the final calculations after the turns per layer and number of layers have been determined from the preliminary data.

For a round winding, with given core, length, size of wire and resistance, the **outside diameter** will be

$$D = \left[\frac{4}{\pi L}\left(\frac{R}{R_s}\right) + D_1^2\right]^{\frac{1}{2}} \tag{48}$$

The approximate **thickness of wall** of winding will be

$$T = \frac{D - D_1}{2} \tag{49}$$

The **number of layers** will be $n = Tn''$, and a new value for $T$ will be found for an exact number of layers, by $T = n/n''$. The **mean length of turn** will be $p_a = \pi(D_1 + T)$ and the **outside diameter** will now be $D = D_1 + 2T$. The **number of turns** will be $N = n''L$, and the **resistance**, $R = Np_aR_l$. For round windings, the **radiating surface** is $A = \pi DL$, where $A$ is the cylindrical surface.

## CONSTRUCTION OF COILS

**105. Methods of winding.** There are two standard methods of winding coils. The original method is to prepare the bobbin for the wire and then to wind the coil by rotating the bobbin in a small special lathe and guiding the wire by hand. The second method involves the use of patented automatic machinery.

| 38 | ..... | ..... | 11,920 | 11,580 | 13,400 |

**107. Insulation.** The use of electromagnets on lighting and power circuits makes it necessary to provide additional insulation between adjacent layers of wire to prevent a breakdown at the points of maximum e.m.f. between layers, when the circuit is suddenly broken. It is customary, therefore, to place one or more wraps of thin paper between adjacent layers which, as a further advantage, makes it possible to wind coils of fine wire evenly in layers. Enameled wire is particularly adapted for this form of coil since the e.m.f. between adjacent turns in a layer is very low; consequently more turns per layer may be obtained and a high activity for the coil maintained.

**108. Form winding.** Coils with paper between successive layers may be wound directly into the bobbin, or into forms, and the coils mounted later. It is customary in such cases to guide the wire by means of a traverse screw or a cam. In one well-known patented method, several coils are simultaneously wound by automatic machinery. Coils wound in a so-called haphazard manner are well named, since the e.m.f. between adjacent wires may be sufficient to puncture the insulation under sudden fluctuation of the current.

**109. Drying and treating.** In general, coils should be thoroughly dried out, dipped in insulating varnish and baked, or else treated with some melting compound. This not only protects them from moisture, but also assists in conducting away the internal heat. Coils wound with tape as a finish should be treated in the same manner as the field coils of electric machines.

**110. Mounting.** A good method of mounting direct-current windings after impregnation is to wrap a thin brass tube with oiled muslin, fringed

Digitized by Google

at the ends so that the fringes will overlap one another when bent at right angles to the tube. The coil is then mounted on the muslin-covered tube and several oiled muslin washers are placed on each end. A slotted fiber washer is mounted at the end with the inside lead, and the lead is brought out through the slot after being wound once around the tube; the inside diameter of this washer should be sufficient to slip over the turn of the lead. More oiled-muslin washers are then put on, and the fringes are fanned out at both ends of the coil, after which heavy fibre end washers are put on and the ends of the brass tube spun over. This makes a very solidly constructed and well-insulated coil. In alternating-current coils, the brass tube must be slotted lengthwise. When flat ribbon leads are used, it is not necessary to use a slotted washer.

All splices should be soldered and thoroughly protected with oiled muslin. The leads should be tied in position with stout twine.

**111. Covering.** Mounted coils are covered with cord, pressboard, oiled muslin, etc., and are often dipped in black air-drying varnish to give them a protecting finish.

## TESTING OF MAGNETS

**112. Measurement of pull.** The attracting effort of a small portative magnet or a small tractive magnet, with the armature or plunger in contact with the pole faces or stop, may be measured with a spring balance. Large magnets may be tested by direct loading or by loading through a system of levers. The **pullout point** is not preceded by any warning and, in order to obtain accurate load readings, the load must be applied at a uniform rate and under perfect control.

A simple method is to hang a bucket below the weights and to pour water or shot into it until an amount equal to a weight unit is exceeded, when the bucket may be removed and the equivalent weight placed in position; then the empty bucket is again hung in place and filled, this cycle of operations being continued until the pullout point is reached, when the total weight is determined.

**113. The pull tests, for various lengths of air-gaps,** may be made by the use of brass discs or rings of thicknesses arranged in decades. Thus the first group may be 1 in., 2 in., 3 in., and 4 in. respectively, with which any combination in thickness from 1 in. to 10 in. may be obtained. This idea may be carried out as far as desired. Twelve spacers will give 1,000 combinations. The measurement of the pull should be made as outlined in Par. **112.**

**114. The heating test** requires an ammeter, a thermometer (or voltmeter), a watch and a rheostat. Fig. 36 shows the connections for a test where the temperature rise is determined by the change in resistance (Sec. 3). Instruments and general measurements are treated in Sec. 3. The temperature rise can be measured either by the resistance method or with a thermometer placed against the outside of the winding. In making the test the current should be kept at a constant value $I$ by means of the rheostat, and the thermometer (or, in Fig. 36, the voltmeter) read at regular time intervals. While making the test, either the temperature or the e.m.f. drop should be plotted with time; this will give the heating curve and show when the final temperature has been reached.

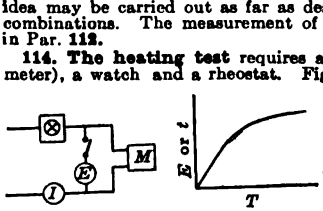

FIG. 36.—Connections for heat run, determining temperature rise by resistance method.

**115. The resistance test** is usually made with a Wheatstone bridge or a modification* of the same designed to test the coils very rapidly.

**116. Test for short-circuited turns.** Coils designed for use on alternating-current circuits are tested for short-circuited turns by placing them on the core of a special transformer, whereby a high e.m.f. is induced in them.

**117. The breakdown test** for direct-current coils is accomplished by placing them on a laminated core before mounting; then heavily overloading

* Underhill, C. R. "The Design of a Quick-acting Wheatstone Bridge," *Electrical World*, 1910, Vol. LVI, p. 29.

Digitized by Google

them, and suddenly interrupting the circuit so as to induce a high momentary e.m.f. A reduction in the resistance of the coil is, as determined by subsequent measurement, an indication of punctured insulation in the winding. Coils mounted on brass tubes covered with six wraps of oiled muslin withstand a regular commercial test, from coil to tube, of 3,500 volts alternating effective value.

# INDUCTION COILS

BY CHARLES R. UNDERHILL

## GENERAL

**119. Induction coils may be divided into two classes:** those with a primary winding only, and those with both primary and secondary wind

Digitized by Google

ings. The former are used almost exclusively in connection with the ignition of internal-combustion motors. The function of both types is to respond to very sudden fluctuations of the e.m.f. in the primary circuit. For this reason, they have open magnetic circuits, which partly accounts for their generally low efficiency.

In telephony, the function of the induction coil is to accurately transform the complex waves of e.m.f. and current corresponding to the sound waves produced by articulate speech. It is, therefore, in this particular case, simply a transformer with an open magnetic circuit. Induction coils of the secondary type are also used in radiography, wireless telegraphy, internal-combustion motor ignition, etc.; they operate on the principle of the gradual or progressive storage of energy, which is then suddenly discharged, and the cycle repeated.

The performance of the primary type of induction coil has an important bearing on the behavior of secondary-type coils of the jump-spark type and, for this reason, the primary-type coil is treated first and separately.

## PRIMARY-TYPE INDUCTION COILS

**120. Definition.** A primary-type coil is a reactor (Sec. 6) designed to receive electrical energy, then convert it into magnetic energy, storing as much of the latter as feasible, and finally to reconvert it suddenly into electrical energy. The ultimate object is to utilize the heat of the resulting spark, when the circuit is suddenly broken. The rupture of the circuit usually takes place in the cylinder of an internal-combustion engine or motor.

**121. Theory.** As commonly made, the primary-type induction coil consists of relatively few layers of coarse magnet wire wound over a core consisting of a bundle of soft-iron wires. When the circuit is closed through a battery, current flows through the coil and magnetises the core; the counter-e.m.f. generated by the lines of flux cutting the turns of wire in the coil opposes the e.m.f. of the battery, so that a definite time interval is required to fully charge the iron core with magnetism.

**The break** is designed to have a snap-action which causes the circuit to be opened very rapidly, as soon as the flux in the core attains its most efficient value; thereupon the current and the flux decrease at a very rapid rate, and at the same rate, to zero. This sudden rate of change in the flux induces a high e.m.f. in the coil, proportional to $\partial\phi/\partial t$, in the same direction as the battery e.m.f., tending to retard the decrease of the current, and thus prevent the sudden collapse of the magnetic field. Hence, at the point of rupture, or break, there results a bright spark or arc, usually varying from $\frac{1}{4}$ in. to $\frac{1}{2}$ in. in length, the energy of which is the equivalent (barring losses) of the magnetic energy previously stored in the core. The value of the current at the instant that the metallic circuit is broken is given in Par. **30**, Eq. 6, under "Magnets."

**122. Stored magnetic energy.** The magnetic energy, in joules, stored in time $t$ is

$$W = \frac{L}{2} I^2 \qquad \text{(joules)} \qquad (50)$$

where $L$ is the inductance in henrys and $I$ is the value of the current in amperes at the end of time $t$ in seconds. This is the **energy of the spark** (less losses).

**123. The inductance of the coil** is expressed by

$$L = 80 N^2 d 10^{-9} \qquad \text{(henrys)} \qquad (51)$$

approximately, for cores having ratios of length to diameter between 10 and 15, where $N$ is the number of turns in the coil, and $d$ is the diameter of the core in centimeters.* The time, $t$, required for the current to attain 63 per cent. of its final value is the **time constant** (Sec. 2) of the circuit; it is numerically equal to $L/R$. By assuming that the rate of current increase is nearly uniform between 0 and $L/R$ seconds, which is approximately correct, the value of the current strength may be estimated for any corresponding time after closing the circuit.

* Armagnat, H. "Induction Coils" (Translated from the French by O. A. Kenyon); New York, McGraw-Hill Book Co., Inc., 1908.

Digitized by Google

**124. Test characteristics.** In Fig. 37 are shown the test characteristics* of a coil with circuit constants of $R=9$ ohms, and $L=0.02$ henry. When the circuit was closed for 0.02 second, with an e.m.f. of 8 volts, the **stored energy** (or spark energy) was 0.025 watt-second. The curve for 12 volts is also shown. It will be seen that the current at any instant is directly proportional to the e.m.f.

The time required for the current to rise from 0 to 63 per cent. of its ultimate value may be lessened by reducing the inductance or increasing the resistance. In general, a gain in time causes a corresponding loss in energy stored. The voltage should be sufficient to overcome variations of the resistance of the contacts, but not great enough to hold the arc too long after the contacts are separated. In practice, battery e.m.fs. of from 6 to 12 volts are employed, but a good rule is to keep the e.m.f. as low as possible. When a generator is used instead of a battery, the resistance and the inductance of the generator must be added to the constants of the rest of the circuit.

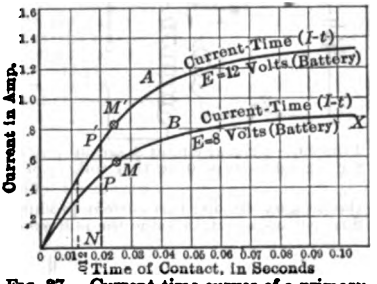

FIG. 37.—Current-time curves of a primary-type induction coil.

**125. Instantaneous current.** Fig. 38 shows an **oscillagram** from a test† of a primary-type coil. The constants of the circuit were $E=4$ volts $R=1$ ohm, $L=0.01$ henry, and the final value of the current, $I$, 4 amp. The circuit was closed at $A$ and the current attained a value of 63 per cent. of 4 amp. at $B$, in 0.01 sec. The metallic circuit was suddenly broken at $B$ and current had ceased to flow, i.e., there was no arc, after the circuit had been broken, for 0.0015 sec. The circuit remained broken from $C$ to $A$, and then the cycle was repeated. If the circuit had been left closed for more than 0.01 sec., the value of the current, for varying time, would have been represented by the dotted logarithmic curve.

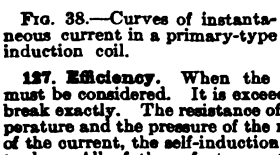

FIG. 38.—Curves of instantaneous current in a primary-type induction coil.

**126. Variation of inductance and resistance.** It will be seen that the amount of energy, $W$, stored magnetically, for a given primary coil, is proportional to the time that the circuit is closed. Owing to the fact that the inductance is not constant, it is difficult to estimate accurately the time-constant of the circuit. A certain amount of resistance is also introduced at the contacts, due to corrosion, etc. For these reasons, the predetermination of the characteristics of such a coil is only approximate.

**127. Efficiency.** When the coil circuit is broken, several variables must be considered. It is exceedingly difficult to calculate the speed of the break exactly. The resistance of the arc at the break depends upon the temperature and the pressure of the medium in which the arc occurs, the strength of the current, the self-induction of the circuit and the material of the electrodes. All of these factors enter into the determination of the time required to reduce the current to zero. Prof. Bailey estimated the average e.m.f. developed at the break, in the coil tested (Par. **125**), to be 30 volts, and the efficiency to be 56 per cent.; however, he considered that the efficiency might be increased to 85 per cent. by increasing the inductance four times and permitting the current to rise to 1.25 amp.

## SECONDARY-TYPE INDUCTION COILS

**128. Theory.** Fig. 39 shows the circuit diagram of a typical secondary-type induction coil. The circuit is closed at *S* and current established in

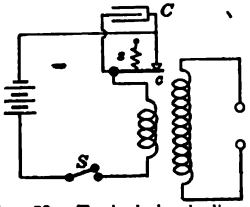

FIG. 39.—Typical circuit diagram for secondary-type induction coil.

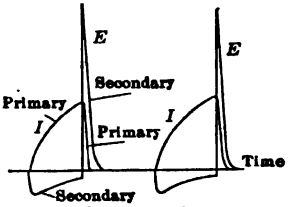

FIG. 40.—Current and e.m.f. curves of a secondary-type induction coil without condenser.

the primary circuit; this current produces a flux in the core and when the flux reaches a certain value the pull exerted on the interrupter contact arm

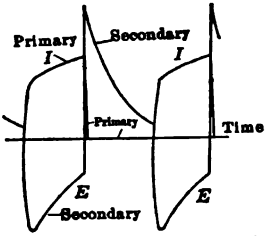

FIG. 41.—Effect of loading the secondary. (No condenser.)

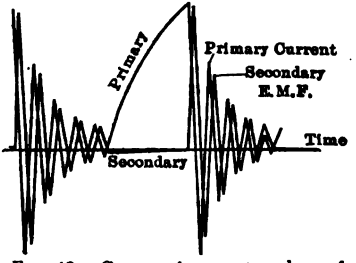

FIG. 42.—Curves of current and e.m.f. in an unloaded secondary-type coil with condenser.

is sufficient to overcome the pull of the spring, *s*, and opens the circuit at *C*. The circuit being open, the flux quickly decreases to zero and thus generates a high value of e.m.f. in the secondary winding, which consists of many turns.

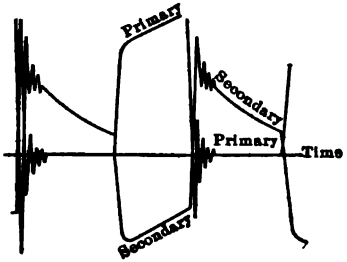

FIG. 43.—Current curves of a loaded secondary-type coil with condenser.

When no condenser (Par. **169**) is used and the secondary circuit is open, no current flows through the secondary and, consequently, the effect of the secondary upon the primary is nil, excepting for the negligible charging current in large coils. All actions in the primary take place exactly as though the secondary were not present. Fig. 40* is the same as Fig. 38 with the secondary e.m.f. curves added. The effect of **loading the secondary** (without condenser) is shown in Fig. 41.

**129. Effect of condenser.** Fig. 42 shows the effect of the condenser

* Bailey, B. F. "The Induction Coil;" *Electrical World*, 1910, Vol. LV, p. 943.

Digitized by Google

(Fig. 39) with an unloaded secondary, while Fig. 43 represents the effects of loading the secondary. These curves (Figs. 41, 42 and 43) are taken from oscillograms made by Prof. Bailey. The condenser, with the local inductance of the primary, constitutes an oscillating circuit. The self-induction in the primary is small; hence the rate of oscillation is high. The oscillations in the primary react upon the secondary, producing an oscillation superimposed upon the logarithmic current curve.

**130. Operation of interrupter.** The interrupter should be so designed that the current may increase to its proper value and the circuit then suddenly open automatically, in order that the rate of change in the flux may be as great as possible. The interrupter is usually made adjustable for this purpose. When it cannot be relied upon to give a sufficiently brief duration of contact, it is safer to increase the resistance of the primary and thus decrease the time-constant, rather than to increase the e.m.f. of the battery. The condenser (Par. **169**) should have just sufficient capacity to prevent sparking.

**131. The design of induction coils** is largely empirical, there being many points upon which there are no definite data. Prof. Bailey and others have published some excellent papers on the theory of induction coils, from which part of the foregoing data have been taken (see "Bibliography").

**132. Core design.** Fig. 44 shows a curve plotted* between flux in lines per square inch per ampere-turn per inch length of coil ($\mathfrak{B}l/NI$), and the ratio of core length to net cross-sectional area of core ($l_c/A_n$). It must be noted that the net area is used; this is given by

$$A_n = a\frac{\pi d^2}{4} = 0.7\,\frac{\pi d^2}{4} \qquad \text{(sq. in.)} \qquad (52)$$

where $d$ is the core diameter in inches, and $a$ is the **space factor** (Par. **134**). This curve was plotted from data taken from tests made on cores of commercial annealed round iron wire 0.062 in. in diameter. In every case, the exciting coil was 3 in. long, and consisted of 191 turns of No. 16 A.W.G. copper wire wound in 4 layers. The flux was measured with an exploring coil of 20 turns placed in the centre and outside of the exciting coil. The points plotted on the curve (Fig. 44) are for a set of cores 1 in. in diameter and of different lengths; the circles plotted on the curve are for a set of cores 4 in. long and of various diameters.

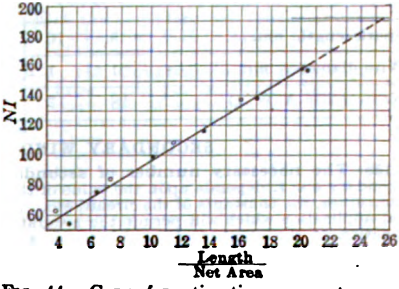

FIG. 44.—Curve for estimating ampere-turns.

It is well to note that the same ratio of length to diameter can correspond to any ratio of length to net area, and that the flux density produced per ampere-turn per inch length of coil varies with the latter ratio.

**133. Flux density.** Based upon the tests plotted in Fig. 44, the flux density along the middle section of the core of a straight-core coil is, according to Mr. O. A. Kenyon,

$$\mathfrak{B}_{max} = \frac{\sqrt{2}\,NI}{l}\left(6.1\,\frac{l_c}{A_n} + 35\right) \qquad \text{(maxwells per sq. in.)} \qquad (53)$$

where $N$ is the number of turns, $I$ the maximum current in amperes, $l$ the length of the coil, $l_c$ the length of the core, and $A_n$ the net cross-sectional area of the core. All dimensions are in inches.

* Kenyon, O. A. from data by Springer, F. W. "The Design and Operation of Spark Coils;" *Electrical World*, 1907, Vol. L, p. 1163.

Digitized by Google

**134. The space factor of the core** is that per cent. of the total area which is occupied by iron. In the cores tested by Mr. Springer, the space factor varied from 0.675 to 0.70 and averaged 0.687.

**135. Table of Core Dimensions from Practice**
(Ehnert) *

| Spark length (cm.) | Core length (cm.) | Core-wire diameter (mm.) | Space-factor |
|---|---|---|---|
| 8 | 15–20 | 0.8 | 0.84 |
| 10 | 20–25 | 1.0 | 0.82 |
| 15 | 25–35 | 1.2 | 0.80 |
| 20 | 30–42 | 1.4 | 0.78 |
| 25 | 35–50 | 1.5 | 0.77 |
| 30 | 48–60 | 1.6 | 0.76 |
| 35 | 52–58 | 1.7 | 0.75 |
| 40 | 62–70 | 1.8 | 0.74 |
| 50 | 80–90 | 1.9 | 0.73 |
| 60 | 100–120 | 2.2 | 0.715 |
| 70 | 120–140 | 2.5 | 0.70 |

**136. The size of the primary wire** should be so chosen as to produce heat at a very low rate, since there is almost no ventilation of the primary coil. The **current density** in the primary coil can vary between 600 and 1,200 amp. per square inch. It must be remembered also that in coils with large cores the **hysteresis** loss is important. See Par. 79.

| Wire diameter, mm. | 1 | 1.2 | 1.5 | 2.0 | 2.5 | 3 |
| Nearest size A. W. G. | 18 | 17 | 15 | 12 | 10 | 9 |

## SECONDARY WINDINGS

**138. The necessary number of secondary turns** to give a certain secondary e.m.f. depends upon the value of the flux in the core, the type of interrupter, the constants of the circuit, etc. As yet there is no law of general application which will permit the accurate or even approximate determination of the number of secondary turns. When the magnetic circuit and the primary winding are finished, an experiment can be made which will determine the approximate number of secondary turns. Using an interrupter that will give a definite and invariable duration of contact, find the value of e.m.f. generated per turn, in a coil of only a few turns, and then divide the total desired e.m.f. by this value to obtain the required number of secondary turns.

**139. Table of Dimensions of Secondary Winding from Practice**
(Ehnert) *

| Spark length, cm. | 5 to 10 | 12 | 15 | 25 | 35 | 50 |
|---|---|---|---|---|---|---|
| *t*, cm. (Fig. 46) | 0.4 | 0.5 | 0.6 | 0.7 | 0.8 | 0.9 |
| *h*, cm. (Fig. 46) | 1.5 | 2.0 | 2.5 | 3 to 3.5 | 4.5 | 6 to 7 |

* Ehnert, E. W. "Theorie und Vorausberechnung der Funkeninduktoren;" *Electrotechnik und Maschinenbau*, 1907, Vol. XXV, pp. 337, 361 and 377.

**140. Limiting the secondary e.m.f.** If too many secondary turns are used, the maximum value of e.m.f. can be limited by connecting the terminals to a **spark-gap**, the length of which corresponds to the maximum permissible e.m.f.

**141. The size of secondary wire** does not vary greatly. For coils giving long sparks, Ehnert states that in practice the wire varies in sizes from those equivalent to No. 35 to No. 38 A.W.G.; and for those coils giving short hot sparks, it varies from No. 30 to No. 34 A.W.G.

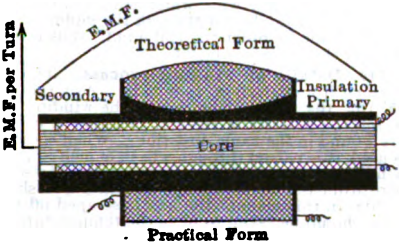

FIG. 45.—Distribution of flux and general form of coil.

**142. Arrangement of windings; layer method.** There are two general methods of arranging the windings, namely, the **layer method** and the section or "**pie**" **method** (Par. 144). Fig. 45 shows the layer method; the upper half shows the theoretical form of the major insulation and the secondary coil, while the lower half shows the practical form. The curve at the top shows the e.m.f. generated per turn in the secondary coil at different positions along the core. This curve shows that turns near the end of the core are very much less effective than near the middle. Designers differ as to the proper length of the secondary coil, but as a rule it varies from 0.25 to 0.50 of the length of the core.

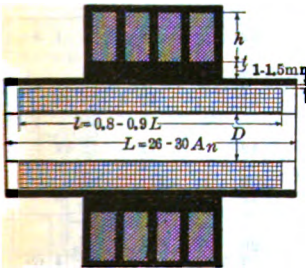

FIG. 46.—Coil proportions.

**143. Construction of secondary-type coils for ignition.** Immense quantities of induction coils are used in internal-combustion motor ignition. These coils usually have secondaries consisting of two sections mounted on a tube over the primary. The coils are wound evenly in layers, by automatic machinery, and several sheets of thin paper are inserted between successive layers during the winding process. These coils are subsequently treated with paraffin or some compound.

**144. Arrangement of windings; "pie" method.** Figs. 47 and 48 show the "pie" method. Coils giving a spark longer than 5 cm. (2 in.) generally require the secondary winding to be made in several sections. In Fig. 47, the inside of one "pie" is connected to the outside of the adjacent "pie," etc., while in Fig. 48, the adjacent coils are connected alternately at the inside and outside. Below the cross-sections are shown the e.m.f. diagrams. In the first, the maximum e.m.f. which can exist between two adjacent coils or "pies" is equal to the e.m.f. generated in one coil and is the same in all parts of the

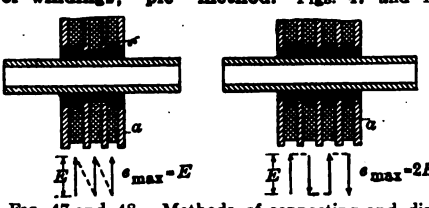

FIG. 47 and 48.—Methods of connecting and distribution of e.m.f. in pancake coils.

Digitized by Google

coil; in the second, the difference in potential between two adjacent coils is zero at the points where they are connected (alternately inside and outside), and increases from that point to a maximum value equal to twice the e.m.f. generated in one coil.

At first sight it appears that the first system would require only half the insulation between sections or "pies" that the second would, but in practice the connecting wire, which must run through the insulation between the coils, is run straight out through the middle and requires sufficient insulation on each side to resist the coil e.m.f.; thus it will be seen that both systems require the same insulation.

**145. Details of winding process.** The pies are wound in thicknesses varying from 0.0625 in. to 0.25 in. As a rule, silk-covered wire is used (Par. **98, 102, 104, 106**). The core of the winding form is given a bevel, in order to tell the polarity of the coil at a glance, provided, of course, that all coils are wound in the same direction. When cotton-covered or silk-covered wire is used, it is passed through a bath of melted paraffin wax or compound while winding; the amount of wax retained by the wire is controlled by passing the wire from the bath through several paper slits, varied to suit the requirements; in this manner the wax is scraped off the wire to any desired extent. Care should be taken to have the temperature of the wax sufficiently high to prevent cooling before it is in place, since the wax serves to hold the wires together. Before winding, the wire should be thoroughly dried out in an oven.

**147. Insulation.** The properties of insulators and other materials are given in Sec. 4 (see index). The **major insulation** between the primary and the secondary generally consists of a tube of such material as ebonite, hard rubber or micanite; or, in small coils, paraffined paper. The new material "Micarta" may also be used. The **minor insulation** is generally obtained by impregnating the coils with paraffin wax or some compound. Over each layer of the primary winding is wound a thickness of paraffin

paper, and between the sections or "pies" of large secondaries there are discs built up of some treated material. The core wires should also be insulated by dipping them in some kind of insulating varnish.

## INTERRUPTERS

**149. Types of interrupters.** Interrupters for induction coils may be divided into two distinct classes, namely; **mechanical** and **electrolytic**. The simpler form of mechanical interrupter (Fig. 49) is suitable for so-called medical coils. It is also used on small spark coils. This type of interrupter is not easily adjusted to different speeds, since it has a natural frequency of its own, and possesses considerable inertia.

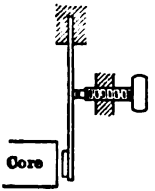

FIG. 49.—Simplest form of interrupter.

**149. An atonic interrupter** is one that can be adjusted to operate at any frequency within very wide limits. A successful interrupter of this type is shown in Fig. 50. Modifications of this type are used on nearly all ignition coils, as well as on large and powerful induction coils. The hammer is attracted by the core and hits the spring contact, making a very sudden break. The duration of contact is regulated with the spring, $s$, and the duration of the break is controlled with the screws, $r$ and $r'$. The spring, $s$, is so attached that it produces a pull which is practically uniform throughout the range of action and thus permits the magnetic force to accelerate the hammer very rapidly. The space between the hammer and the contact spring permits the hammer to attain an appreciable velocity and strike the spring a blow that breaks the circuit very suddenly. The contact spring is light and short, and has a very high natural frequency, thus making the "lost time" very short. This interrupter can be adjusted to operate on alternating-current supply, breaking the circuit when the maximum value of current is reached.

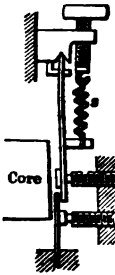

FIG. 50.—Atonic interrupter.

**150. Oil-immersed interrupter.** When the e.m.f. of the source exceeds 20 or 30 volts, the contacts are usually broken in an insulating liquid, which will extinguish the arc.

**151. Mercury interrupters.** For high-speed work, mercury interrupters are extensively used. There are two distinct kinds, namely; the **reciprocating type** and the turbine type. In the former, a reciprocating contact-point is plunged into and withdrawn from a basin of mercury, thus making and breaking the circuit. The plunging contact may be operated in a variety of ways, most usually with a small electric motor. The maximum speed of this type is limited by the tendency of the mercury to follow the plunging contact when it leaves the surface.

In the **turbine type**, a stream of mercury is made to play on a number of saw-like teeth, by revolving either the nozzle or the teeth. When the stream passes between the teeth the circuit is interrupted, and while in contact with the teeth it is closed. This type is almost invariably driven by an electric motor and is excellently adapted to very high-speed work.

**152. Motor-driven interrupters** can be adjusted to operate with alternating current, and are conveniently driven by synchronous motors for this purpose.

**153. Electrolytic interrupters** differ greatly in their characteristics from the mechanical interrupters described above. No condenser is used with this class. The best-known type is that due to **Wehnelt**, which consists of a cathode, generally a lead plate, immersed in a dilute solution of sulphuric acid together with the anode, which is a small platinum wire projecting into the electrolyte from a porcelain tube. The interrupter is adjusted by moving the anode up and down so as to change the amount of surface in action.

When a certain current density at the anode has been reached, the gas released at the surface of the anode increases the resistance at that point

Digitized by Google

to such an extent that the circuit becomes practically interrupted. As soon as the current density falls the resistance decreases and the current again rises to its original value. Experiments show that electrolytic interrupters will operate in synchronism when connected in series or in parallel.

# CONDENSERS

### BY CHARLES R. UNDERHILL

## TYPES

**155. Types and properties of condensers.** There are three principal types of condensers. The most familiar one is the ordinary **plate condenser** used with induction coils, telephone and telegraph apparatus, where a very large capacity is not required. The plate type is also used for laboratory standards (Sec. 3) in measurements of various kinds. Where a very large capacity is required, the **synchronous condenser** (synchronous motor or synchronous converter with overexcited fields) is employed; such apparatus is outside the scope of this Section and will be found under Sec. 9. The third type is the **electrolytic condenser** which is treated later under its own head (Par. 173).

The properties of a condenser are covered fully in Sec. 2, but in brief, the chief function of a condenser is to store electrical energy for subsequent usage. Such storage of energy may take place in a variety of ways, according to circumstances: thus it may be constant, if the condenser is connected to a source of continuous e.m.f., or it may be intermittent, as in the case of a condenser in a telegraph circuit (Sec. 21); or it may be transient; or, in the case of alternating-current circuits, it may be periodic. In consequence of this property of storing electrical energy, condensers can be used in numerous ways to alter or modify the characteristics of circuits in some desired manner, such as to change the relative phase of e.m.f. and current in an alternating-current circuit, improve the power-factor, or to prevent the flow of continuous current simultaneously in the same circuit with an alternating current.

## PLATE CONDENSERS

**156. Types and limits of size.** Plate condensers are made commercially in a number of types, usually designated by the kind of dielectric employed. The earliest type, still used in laboratory and class-room work, is the **Leyden jar**, which is merely a two-plate condenser with a glass dielectric, constructed in the form of a wide-mouthed bottle or jar with tin-foil coatings inside and out. Other types of simple plate condensers are made

Digitized by Google

with various dielectrics, such as air, mica or paper. Increase of capacity is obtained by building up alternate layers of conductor (plate or sheet) and dielectric; alternate sheets or plates are connected in parallel to the two respective terminals. **Rolled condensers** are constructed as a rule of tin-foil and paper, rolled or folded over a mandrel instead of being laid up in flat sheets or stacks.

In the Mansbridge* self-sealing condenser, foiled paper is used which makes it possible to obtain a high capacity for small volume. Before being assembled into the condenser the foiled paper is tested out electrically by running the paper over a metal roll, with the foiled side uppermost, and applying a constant e.m.f. between the foil and the roller. Any weak spots are thus burned out.

The capacity of a Leyden jar is only a very small fraction of a microfarad. Plate or rolled condensers are made in various commercial sizes from a few hundredths of a microfarad up to several microfarads. Condensers having capacities as large as 100 microfarads, for experimental work, have been arranged by connecting a large number of small units in parallel.

**157. The seat of stored energy** in a condenser is in the dielectric. The storage of energy is a consequence of the dielectric displacement, or electric charge in the dielectric, which accompanies or co-exists with a state of electric stress. This displacement is expressed

$$D = \frac{k}{4\pi} E \qquad \text{(statcoulombs)} \qquad (54)$$

where $D$ is the electric displacement or charge, in statcoulombs per cu. cm., $k$ is the dielectric constant or specific inductive capacity, and $E$ is the potential gradient in statvolts per centimeter; the prefix "stat" implies units in the c.g.s. electrostatic system (Sec. 1).

**158. Limits of voltage.** When the electric stress is increased indefinitely, a point is reached at which the dielectric becomes unable to sustain the intensity of stress, and electric rupture occurs, that is to say, the dielectric breaks down. The rupture limit is termed the ultimate dielectric strength. This limit is not a constant quantity under all circumstances, for a given material, but is affected by the shape, size, physical condition, temperature, etc., and by the manner in which the stress is applied. The properties of dielectrics are treated in Sec. 4, under "Insulating Materials." The following table (Par. 159) gives the properties of some of the dielectrics commonly used in condensers.

**159. Table of Properties of Condenser Dielectrics**
(Phillips Thomas)

| Material of dielectric | Specific inductive capacity | Per cent. power-factor | Breakdown strength, volts per mill |
|---|---|---|---|
| Mica | 5.5– 7.5 | 0.05–0.11 | 700–1200 |
| Para. paper | 2.0– 3.3 | 0.10–3.00 | 400–700 |
| Bakelised paper | 4.5– 6.0 | 0.10–4.20 | 300–700 |
| Celluloid | 4.2–16.0 | 0.70–8.00 | 400–900 |
| Aceto-cellulose | 4.5– 6.5 | 0.70–1.10 | 400–700 |
| Gelatine | 4.0– 6.0 | 0.77–8.00 | 400–800 |
| Kerosene | 1.9– 3.6 | | |

These values hold only for sine-waves at 60 cycles per second, at about 20 deg. cent.

**160. Calculation of required dimensions of plate condensers.** The dimensions of a plate condenser are determined by the formula

$$l = \sqrt{\frac{CL_t}{2.24Nk}10^7} \qquad \text{(sq. in.)} \qquad (55)$$

* Mansbridge, G. F. "The Manufacture of Electrical Condensers;" *Journal of Proceedings* of the Institution of Electrical Engineers, 1908, Vol. XLI, p. 535.

Digitized by Google

where $L_t$ is the dielectric thickness in inches, after impregnation, between each pair of metal strips; $N$ is the number of such dielectric strips in the condenser; $C$ is the desired capacity in microfarads; $k$ is the specific inductive capacity of the paper after impregnation, and $l$ is the short dimension of the foil (Fig. 51). This construction insures the lowest possible internal ohmic resistance and also permits the use of extremely thin metal foil.

**161. Internal losses and leakage.** A condenser may have internal losses of two kinds. The first is due to the **resistance of the plates** themselves, and this is most prominent in rolled condensers of very thin tin-foil, inasmuch as each plate is one long continuous strip and the resistance of the whole strip from outer terminal to inner end may be appreciable. The second kind is the loss in the dielectric itself, due to **dielectric hysteresis**, so-called (Sec. 4); this loss can be expressed as an equivalent series resistance, which should be added to the resistance of the plates. Both forms of resistance absorb energy and reduce the normal angle of lead of current with respect to terminal e.m.f. from 90 deg. to some lesser angle; this is equivalent to saying that the power-factor is increased from a value which is theoretically (or in the ideal case) zero to some definite value, although not usually large.

Besides these two forms of loss, there also may be a pure conduction current flowing through a condenser, in phase with the terminal e.m.f., which results from the lack of perfect insulation, or the presence of leakage. The resistance of the condenser to a continuous e.m.f., after the steady state has been reached, is termed the **insulation resistance**. The value of insulation resistance, of course, should be as high as possible.

**162. The power-factor of a condenser** determines to what extent it will be heated when used in alternating-current circuits. The power-factor is the cosine of the angle by which the current leads the impressed voltage, with simple sine-wave forms. It varies with the frequency and impressed voltage, with the temperature of operation, and with the dielectric used. The power-factor of a condenser may be determined by measuring the energy loss or by measuring the variation from 90 deg. phase angle directly.* The specific inductive capacities, power-factors, and breakdown strengths of some materials suitable for condenser dielectrics are given in Par. **159**. The constants of kerosene oil are included for comparison. The values given hold only for 60-cycle circuits, at about 20 deg. cent. The breakdown sine-wave strengths are in effective (root-mean-square) volts per mil thickness of dielectric. In connecting condensers in series for use on high-voltage circuits (static voltmeters and the like), it is important to know the several power-factors, as the distribution of voltage is affected thereby. The voltage distribution among the several condensers will be proportional to the product of capacity by power-factor, for small power-factors.

**163. Absorption of charge.** Many dielectrics do not become fully charged instantaneously, nor do they, when fully charged, give up their complete charges instantaneously. The time lag in receiving full or complete charge is usually referred to as absorption. It is noticeable in testing such dielectrics as glass, rubber, gutta-percha, etc. The effect of absorption on the phase of the current is equivalent to resistance in series with capacity.

**164. Glass condensers** are made both in the form of Leyden jars, and in flat plates. Glass-plate condensers are commonly made of the best plate-glass with sheets of tin-foil shellaced to each side of the plate. The edges of the surface of the plate, not covered with the tin-foil, are varnished to prevent leakage. The finished plates are mounted in a rack and connected together by flat springs which touch the foil of adjacent plates. Condensers of this class are employed on the transmitting side of wireless telegraph apparatus.

L. W. Austin† summarizes the results of his tests as follows: The losses in the **compressed air condenser** used, at a pressure of 15 atmospheres, amount to an equivalent resistance of between 0.1 and 0.2 ohms. Condensers in which "brushing" (brush discharge) is prevented by the nature of their construction show no change in resistance between the limits of observation,

† Austin, L. W. "Energy Losses in some Condensers used in High-frequency Circuits;" Bulletin of the Bureau of Standards, 1912, Vol. IX, p. 73.

Digitized by Google

4,000 to 20,000 volts, indicating that the internal losses are independent of the voltage. Leyden jars of commercial types immersed wholly in oil show losses but slightly greater than those of the compressed-air condenser. The paper and micanite condensers measured show very much larger losses. The resistances of the different Leyden jars in air vary between 1 and 1.8 ohms at 14,500 volts. Between 10,000 and 20,000 volts the equivalent resistance increases approximately in proportion to the square of the voltage. Placing Leyden jars in series parallel, the capacity remaining the same, does not diminish their brushing losses below 20,000 volts. Immersing only the edges of the conducting coatings of Leyden jars in oil gives an equivalent resistance midway between that observed when wholly in air and that when wholly in oil. Brushing losses are much increased by any semi-conducting material on the surface of the glass at the edges of the conducting coatings of Leyden jars.

**165. Mica condensers.** Those condensers in which mica is employed for the dielectric are more constant in their properties than those made with paper. Therefore, mica condensers are used as **laboratory standards** of capacity; and also where high voltage is used, on account of the greater dielectric strength of mica. H. L. Curtis has shown* that with good mica condensers the capacity as measured with continuous e.m.fs. does not differ from the capacity as measured with alternating e.m.fs. more than 0.1 per cent., for any frequency; the difference is usually less than 0.1 per cent. For the effect of temperature on mica condensers, see Par. **167** and Par. **170**. R. Appleyard has shown† that with mica condensers the capacity remains constant with increasing temperature, but the safe voltage limit decreases.

**166. Paper condensers.** According to Mr. Phillips Thomas, plate

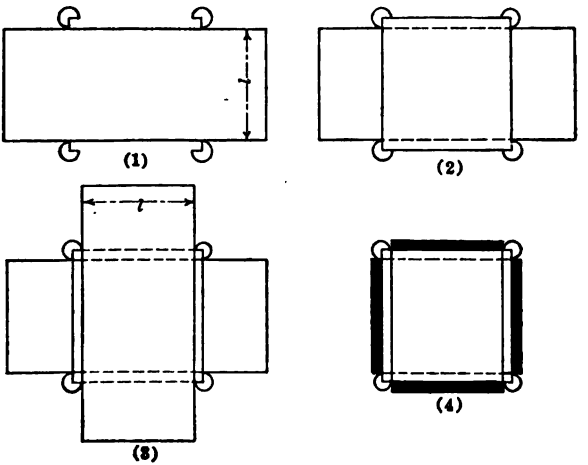

FIG. 51.—Showing the process of building up a multiple-plate condenser.

condensers are made most conveniently and economically as follows: strips of metal foil and squares of unglased paper of close texture and short fibre are piled up in alternation, allowing the metal strips to project on all four sides of the square centre portion. These projecting ends are folded down

* Curtiss, H. L. "Mica Condensers as Standards of Capacity;" Bulletin of the Bureau of Standards, 1910, Vol. VI, p. 431.

† Appleyard, R. "Dielectrics;" *Philosophical Magazine*, 1896, Vol. XLII, p. 148.

Digitized by Google

and melted into one solid bar. The whole is then vacuum dried and impregnated with paraffin, beeswax or the like, and cooled under a pressure not exceeding 10 lb. per sq. in. Fig. 51 shows the method of placing the sheets of foil and paper. The paper sheets are best made in square form, each edge being slightly wider than the narrow dimension of the metal foil. Diagram (1) in Fig. 51 shows four fibre or wooden upright pegs forming a jig, used in building such condensers, with a strip of metal foil laid one way between the pegs; (2) shows a square piece of dielectric (paper) laid over the strip of foil (the pegs are recessed to fit); (3) shows a second piece of foil laid between the pegs, at right angles to the first. This constitutes one element of the condenser. This process is repeated until as many sheets of dielectric as desired have been used, after which the projecting sheets of foil are rolled up and melted into a solid bar, as in (4). The condenser is then ready for impregnation.

**167. Effect of Temperature on Paraffin-paper and Mica Condensers**
(Abst. from Proc. I. E. E., 1896, Vol. XXV, p. 723)

| Temp. deg. cent.... | | 0.4 | 12.5 | 20.1 | 26.9 | 32 | 37.8 | 43.3 |
|---|---|---|---|---|---|---|---|---|
| Paraffin paper. | *R* | 17,740 | 7,216 | 3,622 | 1,947 | 1,231 | 792 | 551 |
| | *C* | 0.98 | 0.98 | 0.98 | 0.98 | 0.97 | 0.96 | 0.95 |
| Mica..... | *R* | 31,427 | 28,427 | 22,000 | 16,272 | 17,010 | 15,270 | 10,521 |
| | *C* | 0.5 | 0.5 | 0.5 | 0.5 | 0.5 | 0.5 | 0.5 |

*R* = effective series resistance, in ohms. *C* = capacity in microfarads.

**168. Table of Commercial Ratings and Sizes of Telephone Condensers**
(Paraffin paper, rolled type, commercial telephone condensers)

| Capacity (mf.) | Dimensions | | | Safe maximum effective voltage | |
|---|---|---|---|---|---|
| | Length (in.) | Breadth (in.) | Thickness (in.) | Continuous (volts) | Alternating (volts) |
| 0.05 | 4.44 | 1.75 | 0.94 | ..... | 1,200 |
| 0.10 | 4.44 | 1.75 | 0.94 | ..... | 1,000 |
| 0.10 | 4.44 | 1.75 | 0.41 | 500 | ..... |
| 0.25 | 4.44 | 1.75 | 1.63 | ..... | 1,000 |
| 0.30 | 4.44 | 1.75 | 1.06 | 750 | ..... |
| 0.50 | 4.44 | 1.75 | 0.53 | ..... | ..... |
| 0.50 | 2.38 | 1.25 | 0.75 | ..... | ..... |
| 1.00 | 4.44 | 1.75 | 0.94 | 500 | ..... |
| 1.00 | 3.00 | 2.38 | 1.00 | ..... | ..... |
| 1.00 | 8.72 | 6.25 | 1.48 | ..... | 1,000 |
| 1.50 | 4.44 | 1.75 | 1.63 | 500 | ..... |
| 2.00 | 4.44 | 1.75 | 1.63 | 500 | ..... |
| 2.00 | 4.38 | 2.06 | 1.13 | ..... | ..... |

It should be kept in mind in considering the above dimensions that the capacity varies directly as the area of the plates and inversely as the distance between them (thickness of dielectric or insulation). Hence the volume per unit of capacity increases rapidly as the safe maximum working voltage increases. Condensers of the rolled paper type are not as a rule tested at less than 500 volts, continuous e.m.f. The insulation resistance should be so high that the leakage is entirely negligible in comparison with the charging current. The cost of such condensers ranges from about 35 cents for the 0.05-mf., condenser, to about 85 cents for the 2-mf. condenser. Also see Par. 171.

**169. Condensers for use with induction coils** and, in general, condensers shunted across gaps to minimize sparking, are usually of the plate type, since it is difficult and expensive to construct rolled condensers having sufficiently low ohmic resistance in their conducting plates. The

Digitized by Google

table of dimensions (Par. 172) applies to condensers used with induction coils.

**170. Effect of frequency and temperature on paper condensers.** F. W. Grover* has made tests of various paper condensers. The following is abstracted from his summary. The capacities and phase differences of 13 commercial paper condensers by different English, French, German and American makers were measured at temperatures ranging from 10 deg. to 35 deg., and at frequencies lying between 33 and 1,000 cycles per second. The

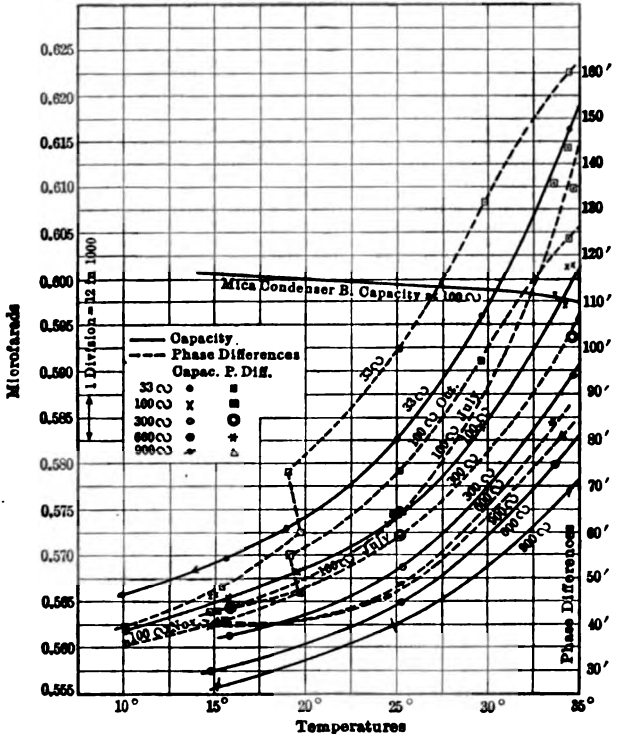

FIG. 52.—The capacity and phase difference of paraffin paper condensers, as functions of temperature and frequency.

results of the measurements are presented in 26 curves, which show, for each of the condensers studied, the change of capacity and phase difference with change of temperature, and the variation of the capacity and phase difference with change of frequency, the corresponding curves of a representative mica condenser being appended for sake of comparison. Fig. 52 shows the curves for the mica condenser referred to, and one of the paper condensers.

* Grover, F. W. "The Capacity and Phase Difference of Paraffine Paper Condensers, as Functions of Temperature and Frequency," Bulletin of the Bureau of Standards, 1911, Vol. VII, p. 495.

Digitized by Google

These curves show that the changes of capacity and phase difference with changes of temperature and frequency are much larger than the corresponding changes with mica condensers. In general, these effects of temperature and frequency are larger as the absolute value of the phase difference becomes larger. The phase differences observed lie between 6 min. and the enormous value of 22 deg. A phase difference of several degrees is not uncommon in commercial telephone condensers. It is shown that the internal resistance of the plates and leads of a paper condenser are often large, especially in the case of telephone condensers made by rolling together sheets of tin-foil and paper. In one example the energy loss in the condenser, external to the dielectric, at 1,000 cycles, was three times as great as the energy loss in the dielectric.

**171. Ratings of commercial paper condensers.** A 2-mf. condenser made by one American manufacturer, using paraffin paper, is 4.5 in. long, 2 in. wide and 1 in. thick, and the price is about 55 cents. The volume per microfarad is 4.5 in. The rated voltage limit is 400 volts, alternating; one of these condensers failed on test at 650 volts, alternating. The energy loss was from 1 per cent. to 2 per cent. Another condenser of the paper type,* built to stand 10,000 volts (alternating), occupied 2 cu. ft. per microfarad. Generally speaking, the ordinary paper condensers of the rolled type used in telephony and telegraphy are built to stand about 500 volts, alternating, and range in size from a few hundredths of a microfarad up to 4 mf. to 6 mf.; some of these condensers are built to stand 1,000 volts, alternating. The higher the voltage limit, the more bulky and expensive the condensers become. The table (Par. **168**) gives the sizes, dimensions, voltage limits, and approximate costs of rolled paper condensers used in telephone practice.

**172. Table of Dimensions of Condensers Used with Induction Coils (Ehnert)†**

| Spark-length, cm | 5 | 10 | 15 | 20 | 25 | 30 | 35 | 50 |
|---|---|---|---|---|---|---|---|---|
| No. of layers | 60 | 65 | 70 | 75 | 80 | 90 | 100 | 150 |
| Dimensions of tin-foil sheets, cm. | 15 by 10 | 17 by 10 | 22 by 10 | 22 by 11 | 25 by 13 | 25 by 17 | 27 by 20 | 32 by 23 |

## ELECTROLYTIC CONDENSERS

**173. Elements of electrolytic condenser.** Certain metals such as aluminum, magnesium, and tantulum, when immersed in an electrolyte, possess the property of allowing electricity to flow in one direction and not in the other, providing a certain critical value of e.m.f. is not exceeded. Two electrodes of this kind practically prevent all flow of electricity and constitute a condenser which is known as an electrolytic condenser. Such condensers are usually constructed with aluminum electrodes and can be made in large units at a cost well within commercial economic limits. The greatest disadvantage of the aluminum electrolytic condenser, as compared with dry condensers, is that it has an appreciable energy loss. Electrolytic condensers used as lightning arresters are usually connected in series with a spark gap so as to avoid the energy loss which would exist were the line voltage continually impressed across its terminals.

**174. The critical voltage** of an electrolytic condenser is the maximum value of impressed e.m.f. which it will stand without permitting an appreciable leakage current. The table in Par. **175** gives the critical voltages for aluminum electrodes with different electrolytes.

**176. The valve effect** of the aluminum anode is due to an exceedingly thin oxide or hydroxide film on the aluminum plate, covered by a thin gas layer, the resistance of which per square centimeter amounts to millions of ohms. Such an anode may be considered as a condenser. In comparing such an anode to an ordinary solid condenser, the gas layer corresponds to the dielectric, while the aluminum electrode and the electrolyte correspond to the two plates of the condenser.

**177. The capacity of this condenser depends only upon the voltage of formation** and the material of the anode, and is independent of the nature of the electrolyte. Fig. 53 gives the capacity as a function of the formation voltage for aluminum, tantalum and magnesium. The abscissas are the voltage of formation, the ordinates, the capacity per square centimeter of surface. The second set of curves in Fig. 53 shows the increase of the calculated ratio ($t/k$) of thickness of the gas layer to the specific electrostatic capacity with increasing formation voltage.

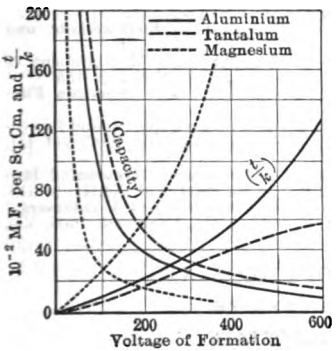

FIG. 53.—Capacity of electrolytic condensers, and ratio of the thickness of gas layer to specific capacity (per sq. cm.).

By passing from lower to higher voltages the thickness of the gas layer increases and assumes its new value within a few minutes. In passing back from higher to lower voltage, however, it requires months before the thickness of the gas layer is reduced again to its former value. For short experiments the thickness of the gas layer may be considered as constant as long as the voltage remains below the voltage at which the anode was formed. In this case the electrolytic condenser behaves like a condenser with interchangeable dielectric. However, if the formation voltage is increased, the capacity is inversely proportional to the formation voltage.

**178. Capacity with reversed currents.** An electrolytic condenser has not necessarily the same capacity in opposite directions of the current. To insure equal capacity in both directions, both electrodes must have an equal surface in the electrolyte and must be formed at the same voltage.

**179. Precautions in manufacture.** In the practical manufacture of electrolytic condensers, attention is paid to the fact that the oxide film and the gas layer adherent to it cover only those parts of the aluminum electrode which are in the electrolyte. From those points of the aluminum surface which are just above the electrolyte, the electricity tends to jump or arc from the aluminum plate into the electrolyte, causing considerable heat and corrosion of the aluminum. It is, therefore, important to make this aluminum boundary line between electrolyte and air as short as possible and to insulate it very carefully.

**180. Electrolytic condensers for alternating-current circuits** should be formed with continuous e.m.fs., equal to the maximum value of the alternating e.m.f.

**181. The energy losses** are small at low voltages and do not increase appreciably when the condenser is connected in the circuit for a long period

Digitized by Google

of time, but as the voltage is increased the losses increase with time at an increasing rate. In cases where condensers are to be used continuously, it is advisable to connect several low-voltage condensers in series. Dr. Gunther Schulze* carried out an extensive investigation of electrolytic condensers in the Reichsanstalt which was described and discussed in an article: "Aluminum Electrolytic Condensers of High Capacity," published in *Electrochemical and Metallurgical Industry*, Vol. VII, p. 216 (1909).

## RESISTORS AND RHEOSTATS

### BY LEONARD KEBLER

### TYPES OF RHEOSTATS

**183. Plate-type rheostats** have a resistance in the form of a reflexed metal wire or ribbon attached to a plate of porcelain-covered cast iron, or to a plate of insulating material such as soapstone, by means of a coating of fused enamel or by cement. They are used almost universally for small field rheostats, theatre dimmers, small motor-speed controllers, battery charging rheostats, etc.

**184. Box-type rheostats** have a resistance in the form of wire-wound, enamel-covered porcelain tubes; cast-iron grids; coils of bare wire; metallic ribbon; carbon discs, or a conducting liquid. They are used for large field rheostats, motor starters, large motor-speed controllers, battery-charging rheostats of the larger sizes, etc. (Also see Par. 197.)

### FIELD RHEOSTATS

**185. Field rheostats** are used in series with the fields of dynamos for regulating the field strength and in turn the voltage of the dynamo, or in the fields of motors for varying the field strength and in turn the speed.

**186. Generator field rheostats** for direct-current machines usually are provided with such a value of total resistance that it is about equal to that

* Schulze, G., "Kondensatoren Grober Kapazität;" *Elektrotechnik und Maschinenbau*, 1909, Vol. XXVII, p. 247.

Digitized by Google

of the field to be regulated, thus giving a variation in field strength from maximum to one-half maximum with a constant exciting voltage.

**Alternating-current generators** have field rheostats whose resistance is usually about twice that of the field, thus giving a variation in field amperes from maximum to one-third maximum, at constant voltage.

**187. Motor field rheostats** have resistances of a value determined by the control desired. The resistance is about equal to that of the field when 25 per cent. speed increase is wanted and may be eight or ten times that of the field when about 400 per cent. increase is wanted.

**188. The current capacity** of a field rheostat should change by an equal amount as each additional step of resistance is inserted. If $I_{max}$ is the current when the rheostat is short-circuited, $I_{min}$ the current when all resistance is in circuit, $N$ the total number of steps and $IN$ the change in amperes per step, then

$$IN = \frac{I_{max} - I_{min}}{N} \qquad \text{(amp.)} \qquad (56)$$

and the current $I_n$ when $n$ steps are in circuit is

$$I_n = I_{max} - nIN \qquad \text{(amp.)} \qquad (57)$$

The total resistance of the rheostat when $n$ steps are in circuit is

$$R_n = \frac{E}{I_{max} - nI_n} \qquad \text{(ohms)} \qquad (58)$$

and when $(n-1)$ steps are in circuit the total resistance of the rheostat is

$$R_{n-1} = \frac{E}{I_{max} - (n-1)I_n} \qquad \text{(ohms)} \qquad (59)$$

The resistance of the $n$th step is therefore $R_n - R_{n-1}$ ohms. In each case $E$ is the e.m.f. in volts at the terminals of the field circuit.

**189. The maximum number of watts to be dissipated by any one step** will be approximately constant, if the change in amperes per step of resistance inserted is constant, and the resistance of each step is figured as above.

**190. The radiating surface** on one side of a plate-type field rheostat in square inches, should be about one-fifth of the total product of $I_{max}$ $I_{min}$ and the total resistance of the rheostat (expressed in amperes and ohms respectively).

**191. The automatic-release feature on motor field rheostats** is sometimes provided. This usually consists of a magnetic device connected across the armature terminals which short-circuits the rheostat resistance when the motor stops, so as to prevent starting under weakened field.

## MOTOR SPEED-REGULATING RHEOSTATS

**192. Speed-regulating rheostats** for main armature circuits have varying amounts of resistance for varying conditions.

**193. The required resistance** for a certain per cent. of speed reduction, with a constant-potential **shunt-wound motor**, is determined as follows: Let $S$ be the normal speed in r.p.m., $S_r$ the reduced speed in r.p.m., $E$ the line voltage, $I$ the current taken at reduced speed, $R$ the rheostat resistance in ohms required to secure the desired speed reduction then

$$\frac{S}{S_r} = \frac{E}{E - IR} \qquad (60)$$

$$E - IR = \frac{ES_r}{S} \qquad (61)$$

and

$$R = \frac{E}{I}\left(1 - \frac{S_r}{S}\right) \qquad (62)$$

**194. Motor current requirements at reduced speed.** For pump, machine duty, etc., the current taken at reduced speeds is approximately that at normal speed. For large ventilating fans the torque varies as the square of the speed, but for ventilating fans of less than 20 h.p., the current will vary more nearly as the speed.

Digitized by Google

**195. Temperature rise of plate-type rheostats.** For each watt dissipated per sq. in. of free radiating surface, the rheostat plate will rise about 100 deg. fahr., and usually but one side of a plate-type rheostat can radiate freely. Therefore where $A$ is the area of one side of the rheostat (sq. in.), $I$ the current flowing (amp.) and $R$ the resistance of the rheostat (ohms) in circuit, the temperature rise will be 100 $(I^2R/A)$ in deg. fahr. (approx.).

**196. A reasonable temperature rise** for box-type rheostats is reached when there is 1 cu. in. of contents for each watt to be dissipated continuously and 1 sq. in. of external surface for each 2 watts to be dissipated continuously.

**197. Calculations of resistance, current-carrying capacity, etc., for box-type rheostats,** regardless of the use to be made of them, may be carried out in the same manner as for plate-type rheostats.

**198. Automatic features on armature speed controllers** consist of no-voltage release, overload release and overload circuit-breaker. **No voltage release** and **overload release** are used with contact arms which are held in the operating position against the action of a spring. On no-voltage or overload the spring is magnetically released and moves the arm to the open-circuit position.

An **overload circuit-breaker** on armature speed controllers consists of a separate switch arm held closed by a latch. On overload this latch is tripped by a magnet, the switch is opened by a spring and breaks the main-line circuit irrespective of the movement of the resistance controlling arm.

**199. Speed regulators for series-wound motors.** For series motors the calculation of the exact resistance for a definite speed variation requires a curve of the motor characteristics. Lacking this it will be found that a controller designed as above for a shunt machine (Par. **193**) will give approximately the same regulation for a series machine running under constant-torque conditions.

## THEATRE DIMMERS

**200. Theatre dimmers** are made of a number of plates mounted in a bank and each plate controlled by its own lever. **A master lever** is usually arranged with cams so that it may control all or any number of the plates

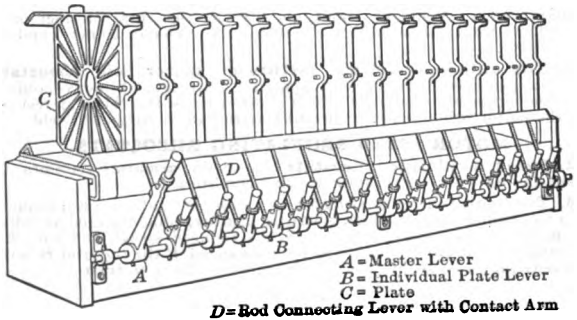

FIG. 54.—Bank of theatre dimmers.

at once. A typical bank is shown in Fig. 54. The circuit operated by one plate seldom carries more than 50 amp. except in the case of the dimmer for the auditorium lights. The latter often carries 300 to 400 amp.

**201. For dimming carbon-filament lamps** a resistance equal to about 3.4 times that of the lamps in the circuit at full candle-power will dim sufficiently so the lamps have no illuminating power. In order that the dimming may be done smoothly and without flicker, 50 steps are required.

**202. For dimming tungsten-filament lamps** a resistance equal to 4 times that of the circuit at full candle-power should be used. In order that

Digitized by Google

tungsten lamps shall be dimmed smoothly and without flicker, the dimmer must have at least 110 steps.

## MOTOR-STARTING RHEOSTATS

**203. Motor-starting rheostats should be so proportioned** that the total resistance and the resistance per step admit sufficient current to start the motor, but not to exceed certain limits.

**204. The normal current** is that necessary to keep the motor armature turning over after it is once started, and is less than the current required to overcome the torque plus the friction of rest in starting from standstill.

**205. The starting current** is equal to the normal current plus a current necessary to overcome the friction of rest at starting, overcome inertia and produce the desired rate of acceleration. In general the starting current is assumed to be one and one-half times the normal current.

**206. Calculation of resistance steps for shunt motors.** Referring to Fig. 55, $I$ is the normal full-torque current, $I_{max}$ the necessary starting current, and $R_7$ to $R_1$ are the several resistance steps, denoting the total rheostat resistance when the contact arm is on each respective point. If the motor field flux is constant (shunt or compound wound), the total resistance in the rheostat is $R_7 = E/I_{max}$. On the first notch, the motor starts with the current $I_{max}$, and as it accelerates the counter-e.m.f. reduces the current finally to $I$. If $e$ is the counter-e.m.f., then the potential drop in $R_7$ is $E - e$. When the second notch is reached, the total resistance is,

$$R_6 = \frac{E-e}{I_{max}} = \frac{IR_7}{I_{max}} \text{ (ohms)} \tag{63}$$

Similarly, when the third notch is reached,

$$R_5 = \frac{IR_6}{I_{max}} \tag{64}$$

and finally

$$R_1 = \frac{IR_2}{I_{max}} \tag{65}$$

If the ratio $I_{max}/I$ is taken as $K$, then it follows that

$$R_2 = KR_1$$
$$R_3 = KR_2 = K^2R_1$$
$$R_4 = KR_3 = K^2R_2 = K^3R_1$$

and

$$R_n = K^{n-1}R_1$$

For practical purposes the ratio $K$ can be taken as equal to 1.5, which is the ratio of $I_{max}$ to $I$.

**207. Number of steps.** In small motors where the armature resistance is comparatively high, 5 steps are sufficient; 9 steps will be ample as long as the difference between the line voltage and the counter-e.m.f. at full speed is not over 4 volts, while in starters for 30-h.p. motors or larger, more than 9 steps are needed to prevent arcing of the contacts.

**208. Current-carrying capacity.** The resistance material is only in circuit during the period of starting, so it need not be capable of carrying the full-load current indefinitely. It should be capable, when cold, of carrying 50 per cent. more than the normal current for 1 min., or 100 per cent. more than the normal current for 20 sec.

**209. Resistance material and filler.** The form of the resistance material is usually coils of bare wire, reflexed ribbon or cast-iron grids. Sand is often used to surround the wire or ribbon, the sand acting as a reservoir to store the heat generated during starting and then to conduct the heat to the walls of the box where it is radiated.

**210. Supports and grids.** Porcelain tubes or other tubes of insulating material are used to support the wire or ribbon when no sand is used, and the resistance is enclosed in a sheet-iron case. When cast-iron grids are used they are usually mounted in a separate case and connected by cables to the rheostat face-plate.

**211. Automatic features for motor starters** are the same as for armature speed controllers, discussed in Par. 198.

Digitized by Google

**212. Starters for series motors.** When the resistance is reduced by cutting out a step, the current increases from $I$ to $I_{max}$ as in the case of the shunt motor (Par. **206**). At once the counter-e.m.f. increases due to the increase in the field current. Consequently, if the same $I_{max}$ is to be used as in the case of shunt motors, the decrease in resistance as a step is cut out, must be larger than in the case of the shunt motor.

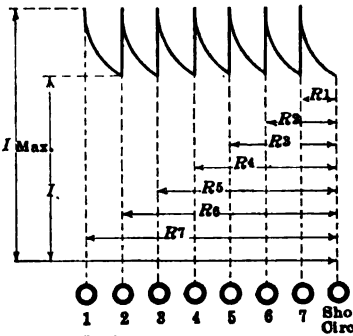

FIG. 55.—Resistance steps for motor starters.

In calculating resistance steps for a series motor which will give the same current curve as shown in Fig. 55, the characteristic curves of the motor must be known. The counter-e.m.f. for any given current is directly proportional to the speed and *vice versa*. In general, however, a starting rheostat that is properly proportioned for a shunt motor may be satisfactorily used with a series motor of the same horse power and voltage.

## BATTERY-CHARGING RHEOSTATS

**213. The resistance of a battery-charging rheostat,** for charging storage batteries from a constant-potential source, may be determined as follows: If $E$ is the e.m.f. of the charging circuit (volts), $E_{min}$ the lowest e.m.f. of the battery during charge (volts), $I_{min}$ the lowest value of charging current, then the total rheostat resistance $R$ will be

$$R = \frac{E - E_{min}}{I_{min}} \quad \text{(ohms)} \qquad (67)$$

A certain amount of this resistance must carry the maximum charging current $I_{max}$; this amount is

$$R = \frac{E - E_{min}}{I_{max}} \quad \text{(ohms)} \qquad (68)$$

The balance of the resistance will have a current carrying capacity varying from $I_{max}$ to $I_{min}$.

## MISCELLANEOUS RHEOSTATS

**214. Wire rheostats.** Wire can be wound in coils, or stretched over insulated frames. Wires larger than No. 6 A.W.G. are difficult to wind in spiral form and wires smaller than No. 21 A.W.G. must be wound upon an insulating core. When it is desired to increase the current capacity of a coil resistor beyond that of No. 6 wire, several coils may be connected in multiple. The table in Par. **215** gives the mechanical dimensions of coils made of different sized wires.

**215. Table of Dimensions of Wire Coils for Rheostats**

| Size, A.W.G. | Max. mandrel, inches | Feet per turn | Turns per inch | Max. coil length, inches |
|---|---|---|---|---|
| 6–8 | 1.25 | 0.38 | 4.0 | 18 |
| 9–11 | 1.00 | 0.30 | 4.5 | 12 |
| 12–14 | 0.75 | 0.23 | 7.0 | 12 |
| 15–18 | 0.50 | 0.16 | 9.0 | 12 |
| 19–21 | 0.25 | 0.082 | 14.0 | 6 |
| 22–30 | Must be wound on insulated core | | | |

*Note.*—The maximum diameter of mandrel given in the table corresponds to the length given therein, and if a stiffer coil is desired a smaller mandrel must be used.

Digitized by Google

**216. Mounting of wire coils.** The finished coils are generally mounted in an iron frame. They are suspended vertically from insulated supports and interconnected so as to give the proper current capacity, and resistance. The total resistance should be divided into units containing a sufficient number of coils in multiple to give the required current capacity and then enough of these units in series to give the required resistance. The terminals of each unit should be brought out and so arranged that the unit can be cut out or short-circuited when it is desired to vary the resistance.

Only fire-proof material should be used in construction of the rheostat. Resistors which are not used continuously, such as starters, etc., can have their heat capacity considerably increased by using plenty of heat-conducting material, which will delay the attainment of the final temperature. The heat capacity and effective radiating surface of a coil resistor can be increased by placing the coils in an iron box filled with sand, oil or some other insulator which is a fair conductor of heat. Coils may be submerged, temporarily, in water when it is desired to increase their capacity for some special purpose. Wire under these conditions can be worked at about four times its normal capacity.

**217. Radiation.** When coils are to be enclosed in a weather-proof box, 0.5 sq. in. to 1 sq. in. of box surface should be allowed per watt dissipated by the resistor. With a good ventilation and about 1 sq. in. per watt the temperature rise will be about 100 deg. fahr. See Par. **195** and Par. **196.**

Wires which contain zinc should not be used where the resistor is likely to be overheated, because they will become brittle.

**218. Water-cooled rheostats for generator tests.** Rheostats made up of galvanized iron wire mounted on wooden frames and submerged in running water are often used to absorb energy when making acceptance tests of large apparatus in the power house. In this case the power dissipated can be assumed as directly proportional to the surface of the resistor.

**219. Carbon rheostats** of the compression type have the advantage of fine adjustment. These rheostats are generally made up of plates held in a frame and the resistance varied by varying the pressure between the plates with a screw clamp. Carbon has a negative coefficient of resistance change with temperature. Carbon-filament incandescent lamps, if heated appreciably, do not make satisfactory rheostats because of the rapid change of resistance with current changes.

**220. Liquid rheostats** are especially adapted to the absorption of large amounts of power and are often used as an artificial load in testing dynamos or as starting rheostats for large motors starting under load. The adjustment is perfectly continuous, but unless there is a provision for short-circuiting the electrodes outside the solution it is impossible to cut out the resistance entirely.

**221. Electrodes for liquid rheostats.** The electrode material is not important so long as it is a good conductor and is not attacked by the liquid. Lead or carbon plates are used with sulphuric acid, copper with copper sulphate, and iron in most other cases. The **current density** should not exceed 1 amp. per sq. in.

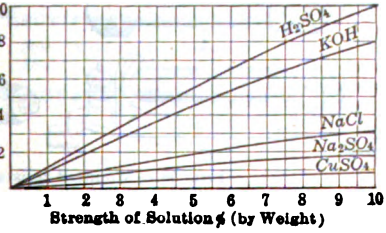

FIG. 56.—Conductivity of solutions.

**222. The solution** depends upon the voltage and upon the quantity necessary to radiate the heat. Pure water is seldom used for pressures under 1,000 volts. For voltages below this, sulphuric acid, or some salt is added to the water to increase its conductivity.

Fig. 56 shows the relative conductivity of various solutions expressed in inches between the plates with a current density of 1 amp. per sq. in.

Digitized by Google

Ordinary water gives a drop from 2,500 to 3,000 volts per in. gap at this current density.

## RESISTANCE UNITS

**223. Resistance units** are used wherever a resistance that is not variable is desired. These units are made in many forms and types for the use of those who desire to purchase the units and assemble them in rheostats; for use in the speed regulators of desk and ceiling fans; for testing purposes, etc.

**224. The resistance material** is usually of German silver or some similar material of low temperature coefficient. This is usually wound on tubes and is then covered with a cement-like coating or with a fused vitreous enamel. The tubes on which the wire is wound consist of pottery, asbestos paper, lava, enameled iron, etc. The enameled iron and pottery tubes are used when the resistance wire is to be hermetically sealed in a fused vitreous enamel.

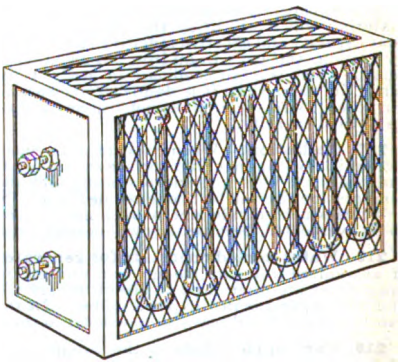

FIG. 57.—Large resistance unit.

**225. Carbon resistance units** are sometimes used where exceedingly high resistances with a very low watt dissipating capacity are desired.

**226. The watt dissipating capacity** ($I^2R$) of such tubular units as are commercially manufactured and listed, varies from 1 to 300 watts. The resistance of these units can be made as high as 16,000 ohms on an enameled wire wound tube 4 in. long and ¼ in. diameter.

**227. Large resistance units** are made of cases enclosing a number of the tubular units described in Par. **224**, or enclosing cast-iron grids, German silver ribbon, etc. (See Fig. 57.)

**228. The temperature rise** of resistance units is as discussed in Par. **195** and **196**.

**229. Mounted resistance units** are manufactured with various attachments for readily mounting in special apparatus or for giving various combinations, etc. Units designed to replace resistance lamps in order that a resistance may be secured that does not change with time, or on account of heat, are so made as to screw into a standard Edison socket. (See A, Fig. 58.) Other units are made with ferrules on the ends, so they may be readily inserted in the conventional type of fuse clips (See B, Fig. 58); still others are mounted in brackets (See C, Fig. 58); on porcelain bases See D, Fig. 58), etc.

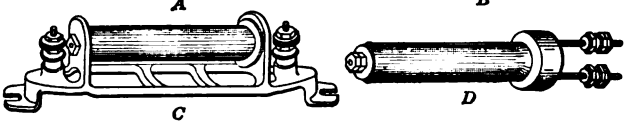

FIG. 58.—Mounted resistance units.

## TRANSFORMERS

### INTRODUCTION

**1. A transformer** is a device for transferring energy in an alternating-current system from one circuit to another. It consists essentially of two independent electric circuits linked with a common magnetic circuit. Thus energy at low voltage may be transformed to energy at high voltage, or *vice versa*. In like manner, current of a given value in one circuit may be transformed into current of another value in a different circuit. The winding of the transformer connected to the supply circuit is referred to as the **primary winding**, and those windings of the transformer that are connected to the receiver circuits are referred to as **secondary windings**.

**2. If a transformer with open secondary winding** has its primary circuit connected across alternating-current supply mains, only a small current will flow through the primary. This current is alternating and produces an alternating magnetic flux in the iron core of the transformer, which interlinks both the primary and the secondary windings and by its rate of change induces an e.m.f. in each. If the two windings are closely associated with each other, the e.m.f. induced in each will be proportional to their respective numbers of turns. The e.m.f. induced in the primary winding is known as the **counter e.m.f.** of self-induction of the primary, or **back e.m.f.**, and is equal in magnitude to the e.m.f. of the mains less the $IR$ drop due to the current passing through the winding. Therefore, if the permeability of the magnetic circuit of the transformer is high and the resistance of the primary winding is low, the counter e.m.f. will be very nearly equal in magnitude to the e.m.f. of the supply circuit, and it follows also that the secondary induced e.m.f. will be nearly equal to the e.m.f. of the supply circuit multiplied by the ratio of the number of turns in the secondary winding to that of the primary winding.

**3. If the secondary circuit is completed through an impedance** or load, current will flow through the secondary and the load; this will tend to demagnetize the core, so that the effective impedance of the primary winding is at once lowered and more current flows into it. The extra current, being just sufficient to overcome the demagnetising effect of the current flowing in the secondary winding, will have the same time-phase as the secondary current and the ratio of the magnitudes of the two currents will be equal to the reciprocal of the ratio of the numbers of turns in the respective windings.

**4. The secondary current causes a drop in e.m.f. in the secondary winding**, partly due to the resistance of the winding and partly due to magnetic leakage caused by the fact that all of the flux which interlinks the primary turns does not interlink all the secondary turns.

**5. The primary current likewise produces a drop of e.m.f. in the primary winding**, due to the resistance of the primary winding and to the fact that there is a portion of the magnetic flux which interlinks some of the primary winding without interlinking any of the secondary winding.

**6. The induced e.m.f.** will therefore be proportional to the e.m.f. of the supply circuit, less the drop in the primary winding; and the secondary terminal e.m.f. will be equal to the secondary induced e.m.f. less the drop in the secondary winding, the drops being taken in their proper phase relations. The total drop from supply e.m.f. to secondary terminal e.m.f. is usually quite small in power transformers, so that the product of the secondary current and terminal e.m.f., measured in kilovolt-amperes, differs from that of the primary by 2 or 4 per cent., only, at full load, while the ratio of the output

Digitized by Google

to the input, or commercial efficiency, may be as high as 99 per cent. at full load.

7. **The ratio of transformation is the ratio of primary voltage to secondary voltage**, or very approximately the ratio of primary turns to secondary turns; it is also approximately the same as the ratio of the secondary current to the primary current.

8. **Constant-potential transformers**, or transformers having nearly constant ratio at all loads, are most generally used for transmission and distribution of power; they are then designated power transformers (Par. 85). When used for the purpose of raising the voltage they are referred to as **step-up** transformers, and when used for lowering the voltage are referred to as **step-down** transformers. If it is desired to call attention to the windings of a transformer without considering their relation to the supply circuit they are termed the high-tension winding and the low-tension winding.

9. **Constant-current transformers** are those in which the current in the secondary or receiver circuit is automatically maintained constant when the primary is connected to a constant-potential source of supply. The mutual inductance varies with the load.

10. **Instrument transformers** are those employed to connect measuring instruments or relays with power mains, the primary being connected to the mains and the secondary connected directly to the instrument. When their function is to transform from the voltage of the supply circuit to a voltage suitable for operating instruments or relays they are termed **shunt-type or potential transformers.** When their function is to transform the current in the supply circuit to a suitable value in the secondary or instrument circuit they are termed **series-type or current transformers.**

11. **Auto-transformers** are those in which the primary and secondary circuits are electrically connected so that part of the load in the receiver circuit is supplied directly from the supply circuit through the primary winding, the remainder being supplied indirectly through the secondary winding by electromagnetic induction.

12. **Transformers may be conveniently classified** as follows:
(a) **Power transformers** for the transmission and distribution of relatively large quantities of energy.
(b) **Instrument transformers** for use with measuring instruments and relays.
(c) **Auto-transformers** for general power purposes, balancing electric circuits, etc.
(d) **Constant-current transformers and regulators**, used for street lighting.
(e) **Voltage regulators**, used for regulating the voltage of alternating electric circuits.

13. **All these different classes of transformers have the same "General Theory,"** which will first of all be discussed: certain considerations in design common to all will next be taken up; and finally the characteristics peculiar to each class will be presented in the order given, together with commercial data.

## GENERAL THEORY

14. **The magnitude and direction of the induced e.m.f.** in a circuit are given in the two laws known as **Neumann's Law** and **Lenz's Law** (Sec. 2). If these laws are applied to the case of the transformer on open circuit the following relations are obtained.

$$\left.\begin{aligned} R_1 i_0 + \frac{\partial}{\partial t}(L_1 i_0) &= e_1 \\ \frac{\partial}{\partial t}(M i_0) &= e_2 \end{aligned}\right\} \quad (1)$$

where $(L_1 i_0)$ and $(M i_0)$ are the numbers of interlinkages of tubes of induction with the primary and secondary windings respectively, $i_0$ is the primary open-circuit or exciting current, $R_1$ is the resistance of the primary winding, $e_1$ is the e.m.f. impressed on the primary winding, and $e_2$ is the e.m.f. induced in the secondary winding.

15. **Practical formulæ for transformers.** If it is assumed that all the turns of the primary and the secondary winding completely encircle

Digitized by Google

a magnetic circuit of uniform cross-section and infinite permeability, and that $e_1$, the instantaneous value of the e.m.f. impressed on the primary, is a simple harmonic time-function of the form

$$e_1 = 10^8 \times \sqrt{2} E_1 \cos \omega t \tag{2}$$

where $E_1$ is the root-mean-square or effective value of the impressed voltage and $\omega$ is equal to $2\pi f$ where $f$ is the frequency of the alternating e.m.f.; $i_0$ becomes zero, and the resulting solution of these equations will give

$$\left.\begin{aligned} (L_1 i_0) &= n_1 A_1 B \sin \omega t \\ (M i_0) &= n_2 A_1 B \sin \omega t \end{aligned}\right\} \tag{3}$$

$$E_2 = -\frac{n_2}{n_1} E_1$$

where $n_1$, $n_2$ are the number of turns in the primary and secondary windings respectively, $E_2$ is the effective value of the secondary voltage, $A_1$ is the cross-sectional area of the magnetic circuit and $B$ the maximum instantaneous value of the induction in C.G.S. lines per unit area. The relations between $E_1$ and $B$ are given by

$$\left.\begin{aligned} B &= \frac{\sqrt{2} E_1 \times 10^8}{\omega n_1 A_1} = \frac{E_1 \times 10^8}{4.44 f n_1 A_1} \text{ (c.g.s. lines per unit area)} \\ E_1 &= \frac{\omega n_1 A_1 B}{\sqrt{2} \times 10^8} = 4.44 \frac{f n_1 A_1 B}{10^8} \qquad \text{(volts)} \end{aligned}\right\} \tag{4}$$

These are the equations used to determine the value of the open-circuit secondary voltage and the induction in power transformers. Even if the reluctance of the magnetic circuit be taken into account the value of $B$ is not materially altered, and since exigencies of manufacture may cause larger errors in this quantity than that due to the assumption of infinite permeability, greater refinement is useless. The error in the value of $E_2$ due to this assumption is not of consequence in most commercial transformers.

**16. The primary open-circuit characteristics of power transformers** may be obtained with sufficient accuracy by means of a curve giving the **loss per unit mass** of iron at different inductions (Sec. 4), and another giving the **exciting volt amperes per unit mass** at different

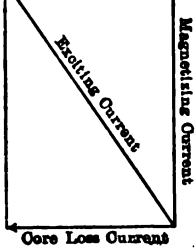

FIG. 1.—Vector diagram of equivalent sine-wave exciting current.

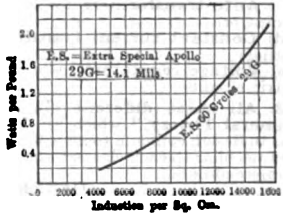

FIG. 2.—Core-loss curve.

inductions. The latter curve is preferably obtained from the average of tests on a number of transformers. Sometimes tests are made on different sizes of transformer cores and the resulting curves plotted separately; this is done to take care of the variations due to building, which are greater in small transformers than in large ones. The value of the exciting current obtained in this manner is known as the **equivalent sine-wave** value. The relations between these equivalent sine-wave values of core-loss current and exciting current as obtained above is shown by vector diagram Fig. 1. Typical core-loss and exciting volt-ampere curves are shown in Fig. 2 and Fig. 3, respectively.

**17. The current in the primary winding of an unloaded transformer**, which has a sine-wave e.m.f. impressed across its terminals, is not a

Digitized by Google

sine-wave, but has harmonic components. This is due to the variable permeability of iron at different inductions and to its retentiveness. The study of the wave distortion due to iron magnetic circuits assumes importance in instrument transformers on account of the possible introduction of error thereby. A knowledge of the properties of different kinds of transformer steels is therefore essential to the design of instrument transformers (Sec. 4).

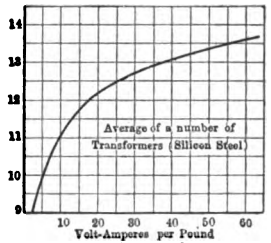

FIG. 3.—Exciting volt-amperes curve.

**18. The secondary open-circuit voltage.** Referring to Eqs. 1, $L_1 i_0$ and $M i_0$ are variables of time, but $L_1$ and $M$ should also be considered as variables depending on the instantaneous value of the induction. Then assuming unity ratio of primary and secondary turns,

$$e_2 = -e_1 + R_1 i_0 + \frac{\partial}{\partial t}\{(L_1 - M) i_0\} \quad (5)$$

where the quantity $(L_1 - M)$ depends on the leakage flux through the windings. This flux will vary directly with the current in the primary, provided that the relative reluctance of different parts of the magnetic circuit remains unchanged throughout the cycle. Hence, if the dimensions of the winding space are large and the permeability of the core is high, even wide fluctuation of value in the latter will produce an inappreciable effect on the total reluctance of the leakage paths. It may therefore be safely assumed that $(L_1 - M)$ is constant at all inductions and Eq. 9, becomes

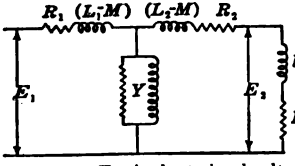

FIG. 4.—Equivalent simple alternating-current circuit for a transformer.

$$e_2 = -e_1 + R_1 i_0 + (L_1 - M)\frac{\partial i_0}{\partial t} \quad (6)$$

**19. Characteristics of a loaded transformer.** The equations of a transformer supplying a load of resistance $R_0$ and inductance $L_0$ are

$$\left.\begin{aligned} R_1 i_1 + \frac{\partial}{\partial t}(L_1 i_1) + \frac{\partial}{\partial t}(M i_2) &= e_1 \\ (R_2 + R_0) i_2 + \frac{\partial}{\partial t}(L_2 + L_0) i_2 + \frac{\partial}{\partial t}(M i_1) &= 0 \end{aligned}\right\} \quad (7)$$

From these equations the following is derived:—

$$\frac{\partial}{\partial t}\{M(i_1 + i_2)\} = e_1 - R_1 i_1 - \frac{\partial}{\partial t}\{(L_1 - M) i_1\} \quad (8)$$

The quantities $(L_1 - M)$ and $(L_2 - M)$ are very nearly constant, but the value of $M$ is dependent on the instantaneous value of the induction. If $i_3$ be taken equal to $-i_2$ to represent the load component of the primary current the transformer may be represented by the following simple alternating current diagram, Fig. 4, where $Y$ is an admittance of such a character as to give an exciting component $(i_1 - i_2)$, which includes the core-loss current. This is known as the "Steinmetz equivalent circuit for a transformer." The current and voltage relations may be given by the vector diagram, Fig. 5, on the assumption that $Y$ is a simple admittance.

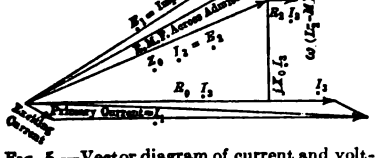

FIG. 5.—Vector diagram of current and voltage relations in equivalent circuit.

Digitized by Google

**20. The short-circuit characteristics of a transformer** are obtained from those of the loaded transformer by making $R_0$ and $L_0$ equal to zero. It is usual to consider the quantity $\omega M$ in the resulting equation as infinite in which case the short-circuited transformer may be treated as a simple impedance so that the effective reactance of a transformer of unity ratio when short-circuited is the sum of $\omega(L_1 - M)$ and $\omega(L_2 - M)$. Moreover under load conditions the effective transformer impedance differs from the short-circuit value only on account of the influence of the normal induction on the permeability of the core, and since the effect of $\omega M$ may be ignored in the short-circuit reactance, the effect due the difference of $\omega M$ under short circuit and when there is normal induction in the iron being of still smaller order of magnitude may also be ignored. The quantities which in transformers under load are the equivalents of the short-circuit copper loss and impedance have been measured with varying inductions in the iron and have been invariably found to be practically constant.

**21. The current in the secondary winding** of a transformer supplying a load may be obtained by means of the simple alternating-current circuit shown in Fig. 4. But since the admittance $Y$ is not readily expressible, it is inconvenient to use this circuit. Moreover the quantity $(L_1 - M)$ cannot be evaluated very exactly and therefore more or less error is introduced when it is used. The following formula derived mathematically from Eq. 6 and 7 with the assumption made in the preceding paragraph has the advantage of great simplicity

$$e_2 = R_0 i_2 + L_0 \frac{\partial i_2}{\partial t} + \left( R_s i_2 + L_\sigma \frac{\partial i_2}{\partial t} \right) \tag{9}$$

where $R_s$ and $L_s$ are the effective resistance and effective inductance when load current is circulated in the secondary with the primary short-circuited.

**22. With sine-wave secondary open-circuit voltages** Eq. 9 becomes that of a simple reactive circuit having resistance equal to the sum of the load resistance and the secondary effective short-circuit resistance and having reactance equal to the sum of the load reactance and the secondary short-circuit reactance. The secondary current may then be multiplied by the ratio of transformation to obtain the primary load current, and from this the primary current is obtained by adding the equivalent sine-wave exciting current in proper phase relation. Eq. 9 under these circumstances may be represented symbolically as follows:

$$E_2 = \{(r_0 + r_s) + j(x_0 + x_s)\} I_2 \tag{10}$$

where $E_2$ and $I_2$ are both vectors, The vector diagram and current loci for all loads are given in Fig. 6.

**23. The construction of Fig. 6** may be explained as follows: $OA = -E_1$ or the primary impressed e.m.f., reversed in time phase. $OB = E_2$, or the secondary open-circuit e.m.f. The radius of the heavy-line circle with $B$ as centre represents the secondary short-circuit impedance of the transformer, drawn to the same scale as $OB$. To obtain the loci of the secondary terminal e.m.f. for any load, bisect $OB$, at $C_1$ and draw the line $C_1$, $C_2$, $C_3$ at right angles. The locus of all loads having a given power-factor is a circle passing through $B$ with its centre at some point on the line $C_3$, $C_1$, $C_2$. The unity-power-factor centre $C_3$, is obtained by making $C_1$, $C_2$ equal to $C_1B$ multiplied by the ratio of the secondary short-circuit resistance to the secondary short-circuit reactance; the centres $C_2$, $C_4$, $C_1$, etc., for loads of other power-factor are obtained by making $\cos \alpha_2$, $\cos \alpha_4$, etc., equal to the respective power-factors, making the angle lag behind or lead the phase of $BC_2$, according as the power-factor is lagging or leading. The loci are then obtained by describing circles passing through $B$ with these centres. The loci for different load currents are concentric circles having $B$ as centre and radii proportional to the respective short-circuit impedance drops at these loads. Thus the secondary terminal e.m.f. with full-load secondary current and 90 per cent. leading power-factor is represented in time-phase and magnitude by the vector drawn from $O$ to the point $C$ where the 90 per cent. leading-power-factor circle intersects the full-load impedance-drop circle. To obtain the loci of the current vectors, describe with centre $O$ a circle of radius to represent the effective full-load secondary current on any suitable scale; with the same centre draw another circle of radius equal to that of the

Digitized by Google

first one multiplied by the ratio of one-half the secondary open-circuit voltage to the secondary short-circuit impedance volts at full-load current. Take $OB$ equal in time-phase and magnitude to the secondary open-circuit voltage, draw $Oc_2$ at right angles to $OB$ and make the angle $c_2Oc_1$ such that its cosine is equal to $\frac{\text{short-circuit reactance}}{\text{short-circuit impedance}}$; draw also a line $c_4c_1c_5$ tangential to the second circle at the point $c_1$; this line is the locus of the centres of the circles passing through $O$, which are the loci of the secondary load currents for different power-factors. $c_1$ is the centre for the circle passing through $O$ which is the locus for the currents for all loads of unity-power-factor; the other centres are found in the same way as for the secondary voltage loci. The loci for different values of secondary load current are circles with $O$ as centre and radii proportional to the effective values of the load currents. The vector for any given value of load current and power-factor of load is therefore the line drawn from $O$ to the point of intersection of the load-current circle and the power-factor circle. The approximate primary current is then obtained by combining this vector with the vector $OE$ representing the open-circuit exciting current.

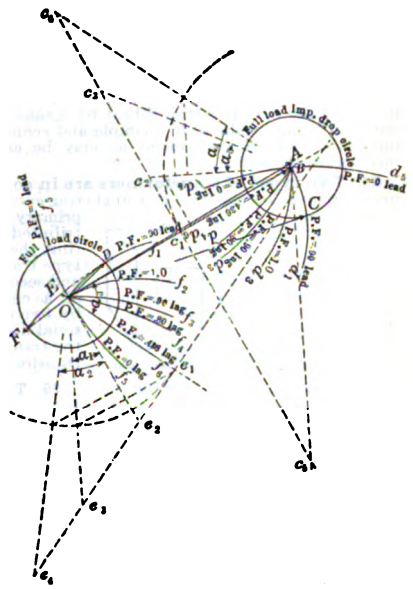

FIG. 6.—Vector diagram showing voltage and current relations in a transformer at all loads.

**24. The short-circuit copper-loss** with full-load current circulated in the secondary winding is not the true copper-loss, but a correction must be made on account of the $I^2R$ loss caused by the exciting current. Part of this extra loss is practically constant at all loads and is included in the core-loss measurements; the other part varies with the load. If $\theta$ be the angle corresponding to the secondary power-factor, $\alpha$ the angle of hysteretic lead, $I_s$ and $I_\epsilon$ the effective values of the exciting current and the component of the primary current corresponding to the secondary current, respectively, then the correction to be added is

$$\text{Correction} = 2I_\epsilon I_2 R_1 \sin(\theta+\alpha) \quad \text{(watts)} \qquad (11)$$

In substituting values of $R_1$ the effective primary resistance should be used. The correct value of induced e.m.f. at which to take the core-loss is the voltage across the admittance $Y$, Fig. 4, and it can be found in the usual way by Eq. 10 after $(L_1 - M)$ has been obtained. But it is not usual or necessary in practice to go to such refinements. The core-loss measured at the rated voltage plus the secondary $IR$ drop is sufficiently close for practical work.

**25. The efficiency** may now be obtained by the usual formula

$$\text{Efficiency} = \frac{\text{Output}}{\text{Input}} \quad \frac{\text{Output}}{\text{Output} + \text{losses}} \qquad (12)$$

**26. The regulation** may be defined as the difference between the full-load and the no-load secondary voltage of the transformer, for the same primary

Digitized by Google

voltage, expressed as a percentage of the full-load secondary voltage, which is also the rated voltage. If $IR/E$ and $IX/E$ are respectively the effective short-circuit ohmic and the reactance drops expressed as fractions of the rated voltage, then

$$\text{Regulation} = \frac{IR}{E}\cos\theta + \frac{IX}{E}\sin\theta + \frac{\left(\frac{IX}{E}\cos\theta - \frac{IR}{E}\sin\theta\right)^2}{2} \qquad (13)$$

## GENERAL DESIGN

**27. The design of successful commercial transformers** requires the selection of a simple form of structure, so that the coils may be easy to wind and the magnetic circuit easy to build. At the same time the mean length of the windings and of the magnetic circuit must be as short as possible for a given cross-sectional area, so that the amount of material required and the losses shall be as low as possible. The form of construction should permit of the easy removal of heat by means of ventilating ducts, it should admit of being insulated in a simple and economical manner, and the windings should be of such forms as may be easily reinforced to withstand mechanical stresses.

**28. Two types of transformers are in common use.** When the magnetic circuit takes the form of a single ring encircled by two or more groups of primary and secondary windings distributed around the periphery of the ring, the transformer is termed a core-type transformer. When the primary and secondary windings take the form of a common ring which is encircled by two or more rings of magnetic material distributed around its periphery, the transformer is termed a shell-type transformer.

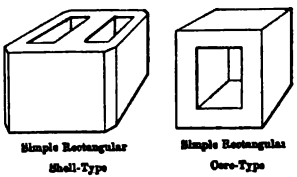

FIG. 7.—Forms of magnetic circuits of transformers.

**29. The characteristic features** of the **core-type** transformer are a long mean length of magnetic circuit and a **short** mean length of windings; those of the **shell-type** are short mean length of magnetic circuit and long mean length of windings. The result of these features is that for a given output and performance the core-type will have a smaller area of core and larger number of turns than the corresponding shell-type. As a general rule the core-type construction is more economical for small high-voltage transformers than the shell-type construction, the dividing line for size being dependent on the voltage. In the matter of relative weights of iron and copper, the two types tend to merge into each other if steps are taken to alter the construction so that their features are more nearly alike. Fig. 7 and Fig. 8 illustrate the forms of magnetic circuits that have been found to result in the most economical and satisfactory designs.

**30. Electrical design.** The fundamental formulæ in the electrical design of a transformer are those given under "General Theory," Par. 15, Eq. 4. If a certain current-density and induction be assumed, the allowable thickness of the coils for the proper cooling may be predetermined. The electrical stress between layers and between adjacent coils may also be predicted with sufficient accuracy to specify the amount of insulation that it will be necessary to use in each case.

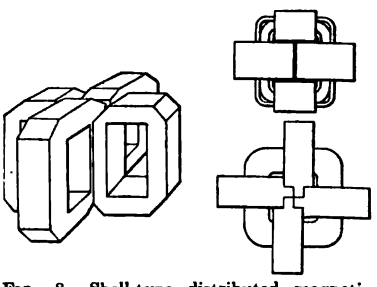

FIG. 8.—Shell-type distributed magnetic circuit.

**31. The area occupied by a primary or a secondary**

Digitized by Google

**conductor,** including the duct space and the insulation clearances necessary to insure proper cooling and insulation respectively, and the proper mechanical allowances may be accurately calculated. Denote these two areas by $a_1$ and $a_2$ respectively and the corresponding net area of the conductors by $\gamma_1$ and $\gamma_2$. Then if $P$ be the out-put of the transformer in watts and $W_1$ and $W_2$ the $I^2R$ loss per lb in the primary and secondary windings at rated output and temperature $\theta$ centigrade

$$\gamma_1 = \frac{P}{E_1} \frac{0.0014\sqrt{1+0.00428\theta}}{\sqrt{W_1}} \tag{14}$$

and $\gamma_2$ may be found by substituting $E_2$ for $E_1$ and $W_2$ for $W_1$. If $A_1$ and $A_2$ be the gross areas of the magnetic circuit and the windings respectively and if $S_a$ and $S_b$ be the corresponding space factors the following relations are obtained

$$A_1A_2 = \frac{\sqrt{2}\,(E_1a_1+E_2a_2)\times 10^8}{\omega S_a B} \tag{15}$$

This may be put in the form

$$A_1A_2 = \frac{\sqrt{2}P}{\omega S_a S_b B}\ 0.0014\sqrt{1+0.00428\theta}\left(\frac{1}{\sqrt{W_1}}+\frac{1}{\sqrt{W_2}}\right) \tag{16}$$

where the mean length of both windings is the same $W_b$ the mean $I^2R$ loss per lb. will be

$$W_b = \sqrt{W_1W_2} \tag{17}$$

It is in general advantageous to have $W_1$ equal to $W_2$. Denote the ratio $A_1/A_2$ by $X$ and let the ratio of the dimensions of the cross-section of the winding space and magnetic circuit be $Y$ and $Z$ respectively. The area and dimensions of the magnetic circuit and winding space will then be

$$A_1 = \left(\frac{A_1A_2}{X}\right)^{\frac{1}{2}},\ \text{Dimensions} = \left(\frac{A_1}{Z}\right)^{\frac{1}{2}} \text{by } (ZA_1)^{\frac{1}{2}} \tag{18}$$

$$A_2 = (XA_1A_2)^{\frac{1}{2}},\ \text{Dimensions} = \left(\frac{A_2}{Y}\right)^{\frac{1}{2}} \text{by } (YA_2)^{\frac{1}{2}} \tag{19}$$

The volume of iron and copper for any type of transformer may be obtained from the formulæ

$$\text{Volume of iron} = S_a(A_1A_2)^{\frac{1}{2}} f_1\left\{X, Y, Z, \frac{C_1}{(A_1A_2)^{\frac{1}{2}}}\right\} \tag{20}$$

$$\text{Volume of copper} = S_b(A_1A_2)^{\frac{1}{2}} f_2\left\{X, Y, Z, \frac{C_2}{(A_1A_2)^{\frac{1}{2}}}\right\} \tag{21}$$

where $C_1$ and $C_2$ are determined from the insulation constants and $f_1$ and $f_2$ denote that the quantities preceding it are to be multiplied by a function of the quantities in the bracket. The quantities in the brackets are not dimensional quantities and therefore $f_1$ and $f_2$ will be independent of the size of the transformer but will vary with different forms. If conditions for minimum cost and loss are introduced, $Y$ and $Z$ become definite functions of the remaining variables so that the functions $f_1$ and $f_2$ may be plotted in sets of curves having $X$ as the independent variable and $\frac{C_1}{(A_1A_2)^{\frac{1}{2}}}$ and $\frac{C_2}{(A_1A_2)^{\frac{1}{2}}}$ as parameters.

**32. The relations between the output of a transformer and its dimensions, weight, and cost of copper and iron,** derived from the above formulas, assuming no change in the space factors, densities and proportions, and provided that the insulation clearances between windings are very small, are approximately as follows:

| | | |
|---|---|---|
| Area of core | varies as | $P^{\frac{1}{2}}$ |
| Area of winding space | " " | $P^{\frac{1}{2}}$ |
| Weight | " " | $P^{\frac{1}{2}}$ |
| Cost | " " | $P^{\frac{1}{2}}$ |
| Per cent. loss | " " | $P^{\frac{1}{2}}$ |
| Volts per turn | " " | $P^{\frac{1}{2}}$ |

(22)

**33. Core material.** **Silicon steel** is used almost entirely for power and distributing transformers. For the first class of transformers chiefly on account of its non-ageing characteristics. For the second class on account of its extremely low hysteresis and eddy current loss. A great deal of investigation is being carried on by various manufacturers with a view of producing steels having characteristics suitable for different classes of work. A complete discussion of various classes of sheet steel for electrical apparatus will be found in Sec. 4.

**34. Insulation, cooling and mechanical stresses.** These factors will have a large influence on the form and dimensions of transformer and are taken up in detail under separate headings below.

## DESIGN OF INSULATION

**35. High insulation strength** is one of the most important requirements of a well-designed transformer. However, provided that the proper strength is obtained at every point, the less insulating material used the better, because the insulating material is the chief factor, limiting the temperature at which it is permissible to operate and it is also the main factor in producing the rise of temperature of the windings.

**36. The electric stresses to which a transformer is subjected in service** may be transient in nature, or they may be steady. Belonging to the former class are surges set up by switching, breaking down of line insulators, arcing grounds, and short-circuits. Steady electric stresses are caused by such accidents as the grounding of one line of a transmission circuit, and will be preceded by a surge or transient wave due to the change in the electric field brought about by the new condition of stress. Thus high electric stress to ground, in a transformer, may be preceded by high stresses between coils and turns of the high-potential parts of the windings. A breakdown between turns in a high-voltage transformer may therefore be due to a combination of the two forms of stress. Another form of stress that may cause breakdown of the low-tension winding is likely to occur when the electrostatic capacity between the high-tension and low-tension windings is high in comparison with that of the low-tension winding to ground, in which case a dissymmetry of the high-tension circuit such as that due to a ground on one line may cause a potential elevation of the low-tension winding sufficient to break down the insulation, or to cause loss of life.

**37. The transient stresses** are difficult to estimate with any degree of certainty and the designer usually has to satisfy himself with results obtained by experience with transformers in service.

**38. The steady stresses** may be easily calculated, and the usual practice is to design the insulation so that it will withstand a difference of potential between the low-tension and high-tension windings and between case and high-tension winding, ranging from two to two and one-half times the possible steady stress under service conditions.

**39. The insulation between adjacent coils and adjacent turns of the transformer** must be capable of withstanding with an ample margin of safety the normal and transient stresses that occur. It is customary in large transformers to give an overpotential test of double voltage, mainly for the purpose of making sure that there are no weak spots in the coil insulation.

**40. Effect of polarity of windings.** Polarity in a transformer depends upon the relative direction of the induced electromotive forces in the primary and secondary windings considered with respect to the two adjacent ends of the two windings.* In a single-phase transformer under normal conditions of service, the middle points of both primary and secondary windings are at ground potential; but the maximum difference between adjacent primary and secondary coils may be half the sum of the primary and secondary voltages or half their differences according to the polarity. This factor becomes of extreme importance in the design of transformer for interlinking two high voltage systems.

* A full discussion of this question will be found in an article by C. Fortescue, *Electric Journal*, 1907, and also one by Wm. McConahy, *Electric Journal*, 1910.

Digitized by Google

**41. Methods of insulating.** The methods employed in insulating a transformer will depend largely upon the type, upon the high-tension voltage, and upon the method of cooling, employed. Small transformers to operate on 2,200-volt circuits are usually insulated between the high-tension and low-tension windings with a cylindrical barrier of mica and fibrous material about $\frac{1}{16}$ in. thick. The usual way of applying this barrier is to wrap it over one winding; the second winding is then wound on top of it. One company uses a tube of mica with a pure shellac bond which has been moulded from a circular cylinder under heat to the proper form with which to insulate the high-tension and low-tension windings from each other. The adjacent ends of the two windings are insulated from each other by means of collars or spacing pieces and heavy paper corner pieces. The complete coil may be vacuum dried and impregnated with a compound insoluble in oil, before the iron is built in, or the iron may be built in first and the whole transformer impregnated.

**42. Insulation between turns and layers.** In small transformers in which round wire is used, and where the volts per turn are small, and the windings are not subjected to high stresses, the cotton covering is sufficient for insulation between turns, and with proper subdivision of the coils only a little additional insulation need be used between layers. In larger transformers where round wires are used, the layers must be heavily insulated. In high-voltage transformers the line coils are sometimes wound with cord between adjacent turns to secure high insulation strength. In large transformers where the conductors are copper straps, the coils are wound spirally with the conductor flat, and the conductor is either heavily sleeved with cambric or cloth, or, according to the practice of one company, the adjacent turns are insulated from each other by micanite strips. The turns of the coils next to the line are always heavily reinforced. In wire-wound coils the voltage per layer rarely exceeds 150 volts in the inner coils and is much less than this in the coils nearest the line.

**43. Coil insulation.** In order to reduce the stress and thereby obtain more effective insulation, the windings are subdivided into coils. The adjacent coils may be insulated from each other by taping, or by insulating washer and edge strips or angle pieces. For insulating the coils of small transformers and air-blast transformers the former method is used by some manufacturers, the coils first being impregnated with an oil-proof gum. For insulating the coils of large oil-insulated transformers the oil spaces between ducts and one or more $\frac{1}{8}$-in. fuller-board washers are depended on.

**44. The insulation between the high-tension and low-tension windings** in large transformers of the shell-type is constructed of sheets of fuller-board about $\frac{1}{8}$ in. thick and angle pieces of the same material. The sheets of fuller board and the angle pieces are arranged in the form of a boxing surrounding each group of high-tension or low-tension coils; all joints are lapped and in high-voltage transformers the corners of the coils are insulated by specially formed angle pieces so that when the insulation of a group of coils is completed, it forms a boxing around the group which completely isolates it from the adjacent group.

**45. Heavy cylindrical tubes of paper** are used between the high-tension and the low-tension windings in large **core-type** transformers. One company uses a paper tube rolled with Bakelite as a bond, the completed tube being "bakelized" after it is rolled; another company uses fibre or fuller-board tubes. **Small high-voltage core-type transformers** may have their high-tension winding wound directly on one of these tubes; this furnishes a cheap and effective method of manufacture.

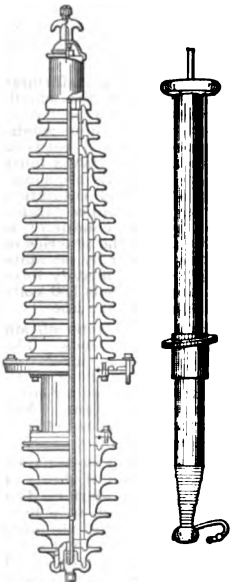
**46. The insulating value of the oil, in oil-insulated transformers,** is depended on very largely to help insulate the transformer; this is done by interspersing the oil and the fuller-board in all the barriers. At the ends of the high-tension coils the insulation is effected mainly by oil spaces reinforced with corner pieces of fibrous material.

**47. In air-blast transformers** the same general method of construction is used, but in addition the coils are heavily taped and treated with waterproof compounds. In air-blast transformers the insulation clearances are very much larger than in oil-insulated transformers, particularly at the ends of the coils where distance insulation must be used to a great extent.

Digitized by Google

**48. Outlet terminals.** One of the most difficult problems encountered in high-voltage insulation design in the past was the provision of a suitable outlet lead. This problem has been solved in two different ways: one is by the use of the condenser-type terminal (Par. **49**), and the other is by the use of an oil-filled bushing (Par. **50**).

**49. The condenser-type terminal consists** (Fig. 9) of alternate cylinders of thin tin-foil and shellac-treated paper, rolled hot on a central brass rod of the proper diameter: they are so arranged that the capacities between adjacent tin-foil cylinders are the same throughout, and the tin-foil cylinders differ in length by equal steps. The potential stress is distributed evenly over the whole length of the terminal. The addition of a disc at the top of the terminal and an external cylinder of insulating material extending between the flange and the disc, the space between the condensers and the cylinder being filled with gum, complete the outlet lead.



Oil-filled terminal — Condenser type terminal

FIG. 9.—Oil-filled and condenser-type terminals.

**50. The oil-insulated terminal** (Fig. 9) depends upon oil as an insulator and as a means for insuring equal distribution of heat in the terminal. It consists of segments of porcelain or moulded material cemented together to form an enclosure for the oil; a conducting rod extends from top to bottom of this enclosure. The oil space is subdivided by insulating cylinders to prevent lining up of particles in the oil.

**51. In transformers for high-voltage transmission** the coils adjacent to the line terminals are more heavily insulated from one another than the rest of the coils. In large transformers the normal stress between adjacent coils is seldom permitted to exceed 15,000 volts. As the size of a transformer is increased, keeping the current density and the coil thickness the same the voltage per coil will vary inversely as the fourth power of the output. Since the thickness of the coils and the spacing between them are usually determined by the cooling requirements, a large transformer is more easily insulated than a small one.

**52. Grounding of the neutral point.** A considerable saving in cost of insulation may be obtained if transformers are designed for operation with the neutral point of the line-circuit grounded. The insulation stresses to which a transformer may be subjected in service are thereby greatly reduced and the danger of breakdown of low-tension insulation due to the effect described in the latter part of Par. **36** is entirely eliminated, in polyphase transformations.

**53. The effect of insulation on cooling** is negligible except in small transformers where the heat has to be conducted through thick insulating barriers, tape on the coils, and heavy layer-insulation; and in air-blast transformers where the temperature gradient through the heavily taped coils may be very large.

## COOLING SYSTEMS

**54. The losses in a transformer appear as heat** in the windings and the core. Means must therefore be provided for removing it; otherwise high temperature will result, which will destroy the fibrous materials used for insulating the various parts of the transformer. **Methods of removing heat** may be classified as follows:

(a) **By natural convection of air and radiation.** This method is employed in certain special cases for small distributing transformers up to

Digitized by Google

25 kv-a. It is the method generally used for cooling instrument and small switchboard transformers.

(b) **By forced convection of air.** Transformers in which this method is used are commonly called **air-blast transformers.** They may be built with ratings up to 5,000 kv-a. and voltages not exceeding 35,000 volts.

(c) **By natural convection and radiation with two fluids.** Oil-insulated air-cooled transformers are cooled in this manner. This method may be applied to transformers for all voltages and for ratings up to 4,000 kv-a.

(d) **By a combination of natural convection of a fluid medium with forced convection of cooling air.** This method has not been used in this country to any great extent, but is in great favor in Europe.

(e) **By natural convection of an insulating fluid which is cooled artificially by another fluid.** This method is used in oil-insulated **water-cooled** transformers.

(f) **By forced convection of an insulating fluid which may be cooled in any convenient way.** This method has been employed to cool large transformers by forcing the cooled fluid through the windings.

Forced oil circulation with the oil cooled by air-blast may be employed in one self-contained unit.

**55. Conduction outward to the surface exposed to the cooling medium** is the first step in the removal of heat from the winding of a transformer. This conduction will partly be through copper and partly through insulation. The flow of heat between parallel faces of any material for a difference of temperature of 1 deg. cent. may be given in watts per sq. in., and in this work it is convenient to express it in this form. The **temperature gradient** at any point of the coil will therefore be opposite in direction and proportional to the maximum value of the heat flux (expressed in watts per sq. in.) at that point.

**56. The maximum temperature rise through a coil** at any point will be the line integral of the temperature gradient in the direction of the heat flow to that point.

**57. The average temperature rise through a coil** at any point of its surface is the weighted average temperature rise of all the portions of the conductors contributing to the heat flow at that point.

**58. Cooling by convection** is the next step in the removal of heat conducted to the surface of the coil. Convection currents are caused by the upward motion of the heated fluid, thereby permitting unheated fluid to displace it. Therefore, it is essential in order to obtain efficient cooling of the coil surface, that the windings be so constructed that they present vertical surfaces, forming paths free from obstructions to the flow of these convection currents. After the heated fluid has risen to the surface it must be cooled, and in order that this may be done efficiently its temperature must be as high as compatible with the limiting value set for the maximum temperature of the transformer. The winding must therefore be so constructed that no part of the fluid flowing past a surface shall be far removed from it; furthermore, the difference in velocity between the fluid in intimate contact with the surfaces of the winding and that furthest removed must be kept as small as possible.

**59. The structural requirements are fulfilled** by arranging the windings so that the exposed surfaces are concentric cylinders with vertical axes or parallel vertical planes. The thickness of the coils is determined by the current-density in the copper and the permissible maximum temperature-rise through the coil.

**60. The physical characteristics requisite in a cooling fluid** in order that it shall be an efficient cooling agent for transformers are:

(a) It must be a good insulator.
(b) It must have good thermal conductivity.
(c) It must have high specific heat.
(d) It must have a high coefficient of expansion.
(e) Its viscosity must be as low as possible.
(f) It must be capable of withstanding the operating temperatures without carbonising or producing gummy deposits on the coil surfaces.
(g) It must be stable, difficult to ignite, and free from acids or any other ingredient that will attack fibrous materials, iron, copper, or varnishes.

Digitized by Google

The reason for most of these requirements are obvious, but (b), (c), (d) and (e) require some explanation, which is given in the next paragraph.

**61. Explanation of heat transfers in cooling fluid.** Consider two adjacent surfaces of a winding taking the form of two parallel planes a small distance apart, and assume that all the heat is emitted in a direction normal to the planes. The fluid directly in contact with the surface will first become heated and expand, thereby becoming lighter and rising. It will thus at every point of its passage assume a temperature which will increase progressively along the vertical. At the lowest point of the coils the oil nearest the surface will perform all the cooling, but as it rises the temperature gradient through the fluid normal to the surface will increase, thus permitting the conduction of heat to the fluid further removed from the surface. The temperature gradient through the oil at the top of the coils will therefore depend upon the velocity of the fluid and its distance from the surface. The more nearly uniform the velocity of the fluid at each point, the less will be the temperature gradient. The velocity of the fluid at each point depends among other things upon the viscosity of the fluid being more uniform the lower the viscosity. High specific heat is important because it permits a given amount of heat to be removed per unit time at lower velocity and lower temperature rise along the surface. High thermal conductivity is necessary so that heat may be transmitted through the fluid normal to the surface with a small temperature gradient. It should be noted that where the fluid is a gas, a certain amount of work is absorbed during expansion, so that the specific heat at constant pressure should be used.

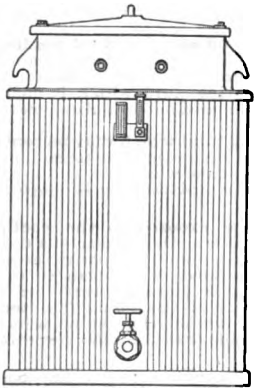


FIG. 10.—Oil-insulated self-cooled transformer.

**62. The temperature difference between the fluid at the top of the coil and that at the bottom** is a measure of the force required to circulate the fluid. Part of this force is used up in overcoming the friction offered by the surfaces and the viscosity of the fluid.

**63. In transformers cooled by free convection in air** the remainder of this force is that necessary to bring the velocity of the air up to the required value to effectively remove the losses. **In oil-insulated self-cooled types** (Fig. 10), where the transformer is immersed in a liquid which circulates by free convection, cooling the surfaces of the windings and being cooled in turn at the surface of the container by convection of the air, the hydraulic force or head developed in the windings due to the difference in temperature has to overcome not only the resistance to flow within the windings themselves, but also that external to the windings due to the sides of the case. In addition to this there is a back pressure or counter-head which represents the force required to overcome the friction resistance of the external surface of the case to the convection currents of air and that required to set them in motion.

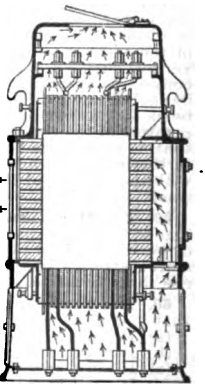

FIG. 11.—Air-blast transformer.

**64. In the air-blast method of cooling** (Fig. 11), instead of depending solely on free convection of air to cool the transformer, pressure is used and air is forced through the windings. The temperature rise of the hottest part of the surfaces, above

Digitized by Google

the incoming air, may therefore be made as small as desired by using sufficient pressure, and the limits of this method of cooling will be set only by the cost of maintaining a large flow of air at sufficient pressure, and by the temperature gradient through the coils and insulation.

**65. Artificial cooling of the hot oil** after it flows from the top of the coils affords the same advantage in oil-immersed transformers (Par. 64). In water-cooled transformers (Fig. 12) this is done by placing a coil of pipe near the surface of the oil, through which cold water is circulated.

**66. In forced oil circulation** (Fig. 13), the liquid is circulated as well as cooled artificially, and a still further gain can be made in efficiency of cooling, but it is only in transformers of large capacity that the gain in cooling efficiency overbalances the increased outlay.

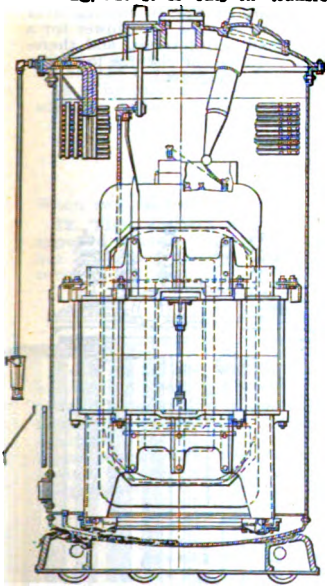

FIG. 12.—Oil-insulated water-cooled transformer.

**67. Limitations in design on account of cooling.** As the size of the transformer is increased, keeping constant the current density, the

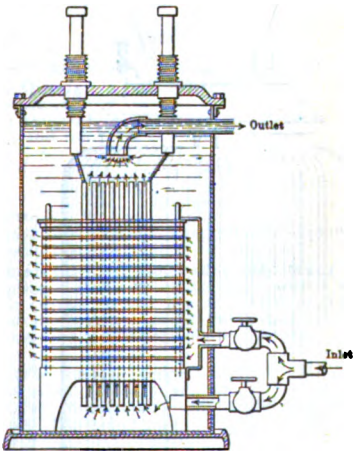

FIG. 13.—Forced-oil circulation system of cooling.

induction and the watts lost per sq. in. of effective coil surface, the dimensions will be proportional to the one-fourth power of the output. The duct area per watt lost will therefore become less, and the length of path the cooling fluid must travel will be greater.

**68. In transformers cooled by natural convection** a larger difference in temperature will be required between the top and the bottom of the coils to set up the necessary circulation of air, the greater the capacity of the transformer, on account of the decrease of the duct area per watt lost and the increase of the mean length of flow path, with increasing capacity or rating. Consequently, unless these factors are changed in proportional ratio with the losses, the temperature rise of this style of transformer will increase as the size increases.

**69. In oil-insulated self-cooled transformers** as the capacity or rating is increased there is more resistance to the flow of oil in the ducts on account of their greater length. Moreover since the dimensions of the case are determined largely by the dimensions of the coils and these are

Digitized by Google

approximately proportional to the one-fourth power of the output while the losses increase as its three-fourth power, the additional surface necessary to dissipate the heat must be obtained by corrugating the tank surface. The air flow has therefore to encounter a more constricted area of entry and a longer path of higher resistance. The volume of air per watt lost will consequently decrease and the average temperature of the air flowing over the surface increase, resulting in a higher average temperature of the oil, unless the gradient between the oil and cooling air has been sufficiently decreased by increasing the tank area per watt lost. The maximum temperature of the oil will tend to be higher, and therefore the maximum temperature of the windings which is the limiting factor in any electrical apparatus will also tend to be higher. Accordingly in large transformers the difference between the average temperature of the air flowing over the surface and the average temperature of the oil must be kept lower for a given temperature rise in the coils than in small transformers, and therefore a larger tank area per watt lost, will be required, or else the temperature gradient through the coils themselves must be decreased.

FIG. 14.— Oil-insulated self-cooled transformer (tubular type).

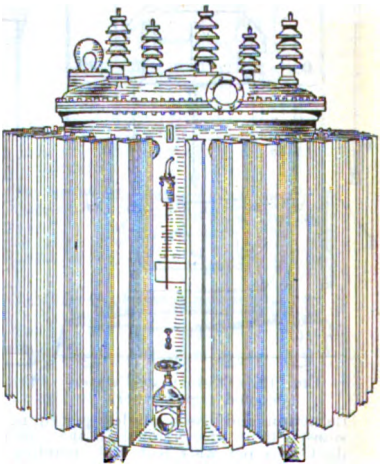

FIG. 15.—Oil-insulated self-cooled transformer (radiator type).

**70. The usual course** is a compromise between these two methods of keeping down the temperature rise in the coils, but with very large transformers this becomes costly and more efficient cooling tanks must be used, good examples of which are the tubular and radiator types of tanks (Figs. 14 and 15) or else recourse must be had to artificial methods of cooling such as water cooling, forced circulation, etc.

**71. The watts lost per sq. in. of coil surface** for cylindrical coils of large radius and for discoidal coils, may be obtained by very simple formu-

Digitized by Google

las from the current-density or the loss in watts per lb. at operating temperature.

$W_s$ = watts loss per sq. in. of coil surface at $\theta$ deg. cent.,
$W_b$ = watts loss per lb. of copper at $\theta$ deg. cent.,
$\gamma$ = area of bare conductor in sq. in.,
$b_0$ = thickness or diameter of wire uninsulated,
$b_1$ = thickness or diameter of insulated wire plus layer insulation,
$n$ = number of turns per layer in layer-wound coil or number of layers in cylindrical coil,
$d_c$ = width of rectangular conductor uninsulated.

$$\left.\begin{aligned} b_0 d_c &= \gamma + c \text{ (for rectangular wire)} \\ b &= s^2 = \frac{4}{\pi}\gamma \text{ (for round wire)} \end{aligned}\right\} \quad (23)$$

where $c$ is the difference in area between a circle having a diameter equal to double the radius of the corners of the conductor and its inscribed square.

**72. The values of $W_s$ (Par. 71) for different types of layer-wound coils** with one surface exposed are

$$\left.\begin{aligned} W_s &= \frac{0.3212 n b_0 d_c}{b_1} W_b \quad \text{(rectangular wire)} \\ W_s &= \frac{0.252\, n b_0^2}{b_1} W_b \quad \text{(round wire)} \end{aligned}\right\} \quad (24)$$

When two sides are exposed the results given above are divided by two.

**73. The temperature gradient through a coil having one surface exposed** may be obtained on the assumption that it is homogeneous, has a thermal conductivity $\lambda_0$ and thickness $\delta_0$ and that the insulation covering has thermal conductivity $\lambda_1$ and thickness $\delta_1$. In which case

$$\left.\begin{aligned} \theta_{max} &= W_s\left(\frac{\delta_0}{2\lambda_0} + \frac{\delta_1}{\lambda_1}\right) \quad \text{deg. cent.} \\ \theta_{mean} &= W_s\left(\frac{\delta_0}{3\lambda_0} + \frac{\delta_1}{\lambda_1}\right) \quad \text{deg. cent.} \end{aligned}\right\} \quad (25)$$

**Coils with two surfaces exposed** are considered as two coils of one-half the thickness with one surface only exposed.

**74. The equation of cooling for an oil-insulated self-cooled transformer** may be based on the assumption that the emissivity of the case is a constant. The calculation is made in two steps: first, the calculation of the mean temperature reached by the oil above the mean air temperature; second, the calculation of the mean rise of the windings above the mean oil temperature. Let

$P_0$ = total loss = $P_1 + P_2$, = iron loss + copper loss,
$\alpha_0$ = emissivity of tank in watts per sq. in. per deg.,
$\alpha_c$ = emissivity of coil surface in watts per sq. in. per deg.,
$A_0$ = area of cooling surface of tank in sq. in.,
$A_c$ = area of cooling surface of coils in. sq. in.,
$\sigma_0$ = specific heat of oil,
$\sigma_c$ = specific heat of coils,
$\theta_0$ = initial temp. rise (cent.) of oil above air,
$\theta_1$ = rise of oil temp. (cent.) after time $t_1$,
$\theta_c$ = initial rise (cent.) of coils above oil,
$\theta_b$ = rise of coil temp. (cent.) after time $t_1$ (hours),
$G_0$ = weight of oil (pounds),
$G_1$ = weight of coils (pounds),
$t_1$ = time measured in hours to raise temp. of oil from $\theta_0$ to $\theta_1$

$$\theta_1 = \frac{P_0}{\alpha_0 A_0} - \frac{\left(\frac{P_0}{\alpha_0 A_0}\right) - \theta_0}{10^{\left(\frac{0.823\,\alpha_0 A_0 t_1}{G_0\sigma_0}\right)}} \quad \text{(deg. cent.)} \quad (26)$$

$$t_1 = 1.215\left(\frac{G_0\sigma_0}{\alpha_0 A_0}\right) \log_{10} \frac{\left(\frac{P_0}{\alpha_0 A_0} - \theta_0\right)}{\left(\frac{P_0}{\alpha_0 A_0} - \theta_1\right)} \quad \text{(hours)} \quad (27)$$

Digitized by Google

The same equations apply to $\theta_s$, and $\theta_b$ if we substitute these values for $\theta_0$ and $\theta_1$ respectively; and also substitute $P$, $A_s$, $\sigma_s$, $G$, and $\alpha_s$ for $P_0A_0$, $\sigma_0$, $G_0$, and $\alpha_0$ respectively; we shall then have the temperature rise of the coils above the oil at the end of an interval $t_1$, starting with a temperature rise $\theta_0$.

**75. In water-cooled transformers the length of cooling coil required** will depend upon the rate of flow of the water. Using the same symbols as before, except that the temperature rises will be measured above the incoming water, we shall have, if radiation from the surface of the tank is negligible and taking $\theta_w$ as the temperature rise of the water, $F$ as the flow in gallons per min., $L$ as the length of cooling coil in feet and $\alpha_w$ the emissivity of the surface of the cooling coil in watts per ft. per deg. cent.,

$$\theta_w = \frac{0.0038P_0}{F} \tag{28}$$

$$L = 606\frac{F}{\alpha}\log_{10}\frac{\theta_0}{\theta_0 - \theta_w} \quad \text{(feet)} \tag{29}$$

Temperature rise above entering water under steady conditions

$$= \frac{0.0038P_0}{F\left[1 - \frac{1}{10^{\left(\frac{0.00165\alpha_w L}{F}\right)}}\right]} \quad \text{(deg. cent.)} \tag{30}$$

Denote the bracketed portion of the denominator of the above fraction by $C$; then,

$$\theta_1 = \frac{\theta_w}{C} - \frac{\frac{\theta_w}{C} - \theta_0}{10^{\left(\frac{2165FCt_1}{G\sigma_0}\right)}} \quad \text{(deg. cent.)} \tag{31}$$

$$t = \frac{G\sigma_0}{2165FC}\log_{10}\frac{\frac{\theta_w}{C} - \theta_0}{\frac{\theta_w}{C} - \theta_1} \quad \text{(hours)} \tag{32}$$

$C$ is constant for a given length of pipe and flow of water. The temperature rise of the coils above the oil may be obtained by the formulas given in the last paragraph. The above formulas with some modification may be used for forced circulation.

**76. The cooling surface required** for a transformer having a rise of 40 deg. cent., based on a room temperature of 25 deg., will vary from 4 sq. in. per watt lost, to 8 or 9 sq. in., according to the size of the transformer. The value of $\alpha_0$ will vary from 0.008 to 0.004 watts per sq. in. per deg. cent.

**77. The following relations will be found useful to transformer designers.** Energy dissipated in 1 lb. of copper at the rate of 1 watt will raise the temperature of the copper at the rate of ½ deg. cent. per min. if no heat be permitted to escape. Water flowing at the rate of 3.8 gal. per min. will absorb 1,000 watts, with a temperature rise of 1 deg. cent. Air, at atmospheric pressure, flowing at the rate of 1,650 cu. ft. per min. will absorb 1,000 watts, with a temperature rise of 1 deg. cent.

## MECHANICAL DESIGN AND COIL GROUPING

**78. Mechanical stresses in service** are due to the heavy currents developed in electrical apparatus under short-circuit, caused by the tremendous amount of energy developed in modern electrical systems. Reactance in a transformer, on account of the great length of the leakage paths in air, furnishes practically the same protection to connected apparatus as an air reactance.

**79. Coil grouping and reactance.** The reactance of a transformer depends on the grouping of the high-tension and the low-tension windings. The same general principles apply to the grouping of the windings of any type of transformer. The element of a given grouping is formed by a set of high-tension and low-tension coils of equivalent number of turns, generally an even submultiple of the total number of turns, placed as near together as

Digitized by Google

the insulation will permit. This is termed a group and is designated thus: *HL* or *LH*. A grouping arranged thus, *LHHL*, is a symmetrical *2HL* grouping; a group arranged thus, *LHHLLHHL*, is a symmetrical *4HL* grouping, and so on. Given a stated number of turns, and a thickness of insulation between high-tension and low-tension windings very thin compared with the coil spaces, the reactance varies approximately as the reciprocal of the square of the grouping. A convenient method of calculating reactance is to consider both the high-tension and the low-tension coils in a given element as each concentrated into a thin shell one-third of the combined thickness of the coils from the surface next to the insulating barrier between the high-tension and low-tension coils.

**80. Influence of mechanical stress on design of winding.** High reactance may be obtained in three ways: (a) By reducing the grouping; (b) by increasing the number of turns; (c) by increasing the spacing between coils. The methods (a) and (b) increase the mechanical stress for a given value of current, while the method (c) decreases it, but the latter is costly; a compromise between these methods is best. All of the coil groups are subjected to compressive forces during short-circuit, and must therefore be properly supported. To prevent buckling of the coils under short-circuit, one company uses two heavy T-beams, spread apart by two end-studs equipped with threads and nuts for the purpose. The end-frames should be provided with heavy brackets against which the outer coils can be braced by set screws, and a heavy wooden board backed by boiler plate or a piece of channel-iron.

**81. Formulas for reactance.** The reactance in ohms is equal to $\omega L$, where $L$ is given in henrys. The value of $L$ may be obtained by the following formulas:

**Shell-type discoidal coils** (Fig. 16);

$$L = \frac{10.6n^2(l_1 + l_2)(2Nc+b)}{N^2(a_1+a_2)\times 10^9} \text{ (henries)} \quad (33)$$

**Shell-type cylindrical coils** (Fig. 17);

$$L = \frac{10.6n^2(2Nc + a)}{N^2b\times 10^9} \text{ (henries)} \quad (34)$$

**Core-type rectangular-core concentric coils** (Fig. 18);

$$L = \frac{10.6n^2(l_1 + l_2)(2Nc+a-d)}{N^2(b_1+b_2)\times 10^9} \text{ (henries)} \quad (35)$$

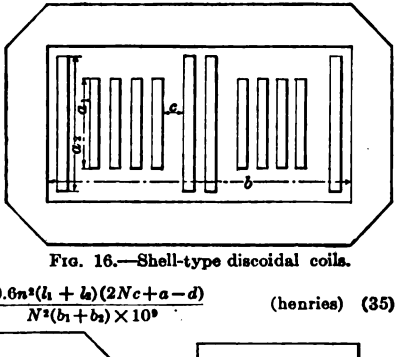

FIG. 16.—Shell-type discoidal coils.

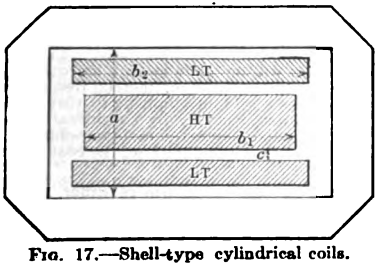

FIG. 17.—Shell-type cylindrical coils.

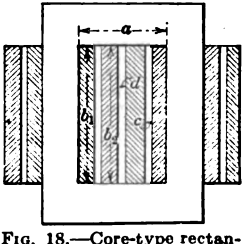

FIG. 18.—Core-type rectangular core concentric coils.

Where $n$ is the number of turns in the winding, $l_1$ $l_2$ are the primary and secondary mean length of winding, $l$ is the mean length of complete winding,

Digitized by Google

$N$ is the number of $HL$ groups, $c$ is the space between adjacent high-tension and low-tension windings, and $a_1$, $a_2$, $b_1$, $b_2$, $b$ and $d$ are as shown in Figs. 16 to 18.

**82. Formulas for mechanical force exerted on coils.** In a transformer the electrokinetic energy is given by

$$W = \frac{1}{2} L I_1^2 \qquad \text{(Joules)} \qquad (36)$$

where $I_1$ is the primary current, and therefore since $F = \frac{\partial w}{\partial x}$

$$F = \frac{1}{2} I_1^2 \frac{\partial L}{\partial x} \times 10^7 \qquad \text{(dynes)} \qquad (37)$$

$x$ being in the direction of the maximum force, that is, at right angles to the surface of the coils. For shell-type transformers with discoidal coils,

$$F = \frac{1}{2} I^2 \left[ \frac{4\pi n^2 (l_1 + l_2)}{4.45 \times 10^7 N^2 (a_1 + a_2)} \right] \qquad \text{(lb.)} \qquad (38)$$

**83. Mechanical design of cases.** Where fluted cases are used they should be made of ingot steel at least 0.079 in. thick, except for transformers below 100 kw., then $\frac{1}{16}$ in. may be used. Cases for oil-insulated self-cooled transformers have the sides cast in a base of cast iron. Boiler-iron cases such as are used for water-cooled transformers are usually guaranteed to withstand a pressure of 50 lb. per sq. in. The covers of large transformers are provided with vents to release the pressure if an explosion should take place. The tank is provided also with a large gate valve, so that the oil may be drawn off very quickly. The cases of large transformers should be made as nearly air-tight as possible, as this prevents dirt or moisture finding its way into the tank.

**84. In the design of end-frames for large transformers** there is a tendency to replace cast iron by structural and cast steel; the weight of the end-frame is thereby much reduced for a given strength; moreover, when structural steel is used, or a combination of structural steel and steel castings, a much greater latitude is given the designer, as he then has freedom to make the proportions of the core anything he pleases. The cooling coils of water-cooled transformers are usually made of $\frac{3}{4}$- to 1-in. brass or iron pipe and are tested up to 250 lb. per in. hydraulic pressure.

## TRANSFORMERS FOR POWER SERVICE

**85. General consideration in design.** The most important quality in a power transformer is **durability**; it should be able to withstand the most exacting conditions to be met in service without being sensibly weakened. It is important that the insulating material shall not be subjected to excessive temperatures, and therefore every portion of the coil surfaces should be well exposed to the cooling medium. The coils directly connected to the lines in high-voltage transformers should have reinforced insulation.

**86. The cheapest transformer consistent with durability** that has a reasonably good performance, is what is generally required. Such features as efficiency and regulation are usually of secondary importance. The flux-density in the iron of such a transformer will be made as high as consistent with a reasonable exciting current; the loss per lb. at commercial frequencies in silicon steels is so low that the core-loss is seldom a limiting feature. The current-density, on the other hand, is limited chiefly by considerations of cost, because when the density is increased beyond a certain point, for a transformer designed to operate at a given temperature rise, the cost begins to increase again.

**87. Types and characteristics.** Power transformers differ mainly in the methods used to cool them: the characteristics pertaining to different methods of cooling are taken up under "Cooling" (Par. 54 to Par. 77). Transformers cooled by natural circulation of oil and air must be designed on a more liberal scale than water-cooled transformers, or those cooled by forced oil circulation, and therefore the losses will be lower in the former than in the latter. Air-blast transformers, on account of the heavy insulation and large insulation clearances needed, are not as efficient as other power transformers of the same voltage-class.

Digitized by Google

**88. Large transformers for general power service** are usually built in one of the following types: self-cooled in tubular or radiator tanks; water-cooled; oil-insulated with forced circulation of air; forced-oil-circulation type; or air-blast. Their characteristics are moderate efficiencies, low temperature rise, and durability. They may be either of the shell-type or the core-type of construction, according to size and voltage; if of the latter type, cruciform cores are used.

**89. Three-phase transformers.** Two types are in general use, viz., the **core-type** and the **shell-type.** The core-type is illustrated in Fig. 19. It consists of a magnetic circuit having three "legs," each of which carries the flux due to the winding of one phase; since these fluxes flow toward a common point the third harmonic must be entirely absent. It is possible, therefore, to use a star-star connection with this type of transformer without producing voltage distortion. The shell-type three-phase transformer does not differ materially from three single-phase transformers; Fig. 20 illustrates such a type of transformer.

It will be noted that a small amount of iron is saved, but the total saving over three single-phase transformers is small. But there is a decided gain in cost of installation of one three-phase transformer over three single-phase transformers, and it occupies considerably less floor space.

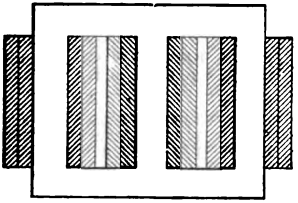

FIG. 19.—Core-type three-phase transformer.

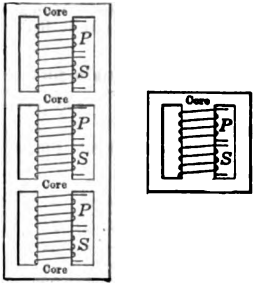

FIG. 20.—Shell-type three-phase transformer; shell-type single-phase transformer of one-third rating shown for comparison.

**90. Transformers designed for outdoor service** may be installed at a lower cost than the standard type, since no housing is required. They are particularly applicable to cases where the amount of energy sold per annum does not warrant a large outlay in installation. A transmission company by using these transformers is enabled to sell energy to small consumers along the right of way. In electrical design they differ in no respect from the standard power transformers, except that the outlet terminal is designed for outdoor service.

**91. The design of the outlet terminal for outdoor service** is not very different from the design of an indoor bushing except that, on account of the rain test it must needs stand, it is usually longer and in the condenser type the terminal proper is encased in a sheath of porcelain petticoats or bells nesting into each other and sealed with a cement. The space between the terminal and the porcelain sheath is filled with a gum of high specific inductive capacity and high melting-point.

**92. Voltage classification.** Standard transformers are classified according to the voltage of the transmission lines on which they are intended to operate. The voltages which are considered standard are as follows:

| | | |
|---|---|---|
| 2,200 | 22,000 | 88,000 |
| 6,600 | 33,000 | 100,000 |
| 11,000 | 44,000 | 110,000 |
| 16,500 | 66,000 | |

Transformers designed for these voltages are usually provided with **taps**

Digitized by Google

so that they may be used for lower voltages. The usual secondary distributing voltages are considered standard. Transformers used for interconnecting two high-voltage systems are considered special.

**93. A standard transformer is completely specified when** the method of cooling, the frequency of the circuit (either 25 or 60 cycles), the voltage class, and low-tension voltages are given. Manufacturers have type numbers or letters for their standard lines, and in some cases they have two lines to offer, or two different lines may overlap for a few sizes. In general, however, no ambiguity will exist if the method of cooling is specified with the other data required.

**94. Tables giving ratings, efficiencies, regulation and weights typical of standard single-phase oil-insulated air-cooled transformers.** These transformers have a guaranteed temperature rise not exceeding 40 deg. cent. at continuous full-load rating. When run continuously at one and one-fourth load the guaranteed rise is 55 deg. cent. above the air; room temperature to be 25 deg. cent. The insulation tests are in accordance with the Standardisation Rules of the A. I. E. E. The tables follow in Par. 95 to Par. 102.

**95. Single-phase—60 Cycles—11,000-volt Class**

| Kv-a. | Efficiencies | | | | | Regulation | | Net weight including oil |

**114. Efficiencies, regulation and weights typical of three-phase oil-insulated water-cooled transformers** may be obtained with reasonable accuracy by taking the values for single-phase transformers of one-third the rating; the water rates and weights being multiplied by three.

## TRANSFORMERS FOR DISTRIBUTING SYSTEMS

**115. General considerations in design.** Transformers for distributing systems should be of high efficiency. Competition has brought about a certain degree of standardization of the losses of each size of transformer. The problem is, therefore, to produce a design having a minimum cost which is durable in service and conforms to definite performance specifications.

**116. The relative values of core-loss and copper-loss** in lighting transformers have been largely determined by competition, but it is probable that the present values give about the best average results in service.

Digitized by Google

**117. The two types of transformers, viz., the shell-type and the core-type are both used for distributing transformers.** The form of shell-type shown in Fig. (8) has shorter mean length of winding and magnetic circuit than the usual form. The dividing line between shell-type and core-type design depends both upon voltage and rating. The former being more economical for low-voltages and large ratings and the latter for high voltage and low ratings. It is usual however to have one type for a line of transformers. The core-type is better adapted for direct cooling in air than the shell-type.

**118. Standard lighting and power transformers** are designed for operation on 60-cycle circuits and have a nominal primary voltage of 2,200 volts and secondary voltages of 220 volts and 110 volts. The **temperature guarantees** for these transformers are usually 45 deg. cent. above atmosphere after 8 hr. full-load run, and 55 deg. after continuous full-load run. Some manufacturers guarantee a temperature rise of 60 deg. cent. at 25 per cent. overload for 4 hr., starting with the oil temperature obtained under no-load conditions. The **insulation test** is usually 10,000 volts, for 1 min., between high-tension and low-tension windings and ground; an overpotential test varying with different manufacturers from double to five times normal voltage is also applied.

**119. Ratings and efficiencies.** The accompanying data (Par. **120** to Par. **125**) on standard lighting transformers have been chosen as giving a fair representation of the general practice in the United States. Two types are manufactured for 2,200-volt 60-cycle service, namely, a "High-efficiency Type" or (standard) and a "Low-efficiency Type." The former type should be used when the cost of energy is high and when it is desirable to operate at high efficiency both all-day and underload. The latter type is justifiable for installation when the cost of energy is low, and where it is not so essential to have a high-operating efficiency. The table (Par. **120**) gives performances of "standard" or "High-efficiency" lighting transformers. The remaining 60-cycle transformers are designed for operation on circuits of higher voltage than 2,200 volts and therefore have correspondingly lower performances.

**120. Performances of 60-cycle Lighting Transformers; Standard Voltages 2,200–1,100/220–110**

**126. Manhole transformers.** It is the general practice in large cities to supply energy for lighting by means of underground cables. Manhole transformers are simply lighting transformers fitted with cases of a type suited for operation in a manhole. These cases are rendered water-tight and air-tight and have an extra amount of radiating surface. The cover is provided with a vent covered by a thin air-tight metal diaphragm, so that if the pressure in the case becomes excessive the diaphragm will rupture. The outlet bushings should be so designed that they are moisture proof and yet admit of ready disconnection of the transformer. The rating, efficiency and regulation are the same as for standard distributing transformers.

## MULTIPLE OPERATION

**127. General principles.** In Par. 19 of this section it is shown that the transformer of unity ratio may be represented by a simple alternating-current circuit shunted by an admittance $Y$. Where the ratio is not unity, this equivalent circuit still holds, if one winding is taken as the reference winding and all admittances are reduced to terms of this winding; this may be done by multiplying (or dividing) all these quantities in the other winding by the square of the ratio. The admittance $Y$ does not enter the problem of relative division of the load and may therefore be ignored; the effective impedance of the transformer with respect to the reference winding will then be the same as the short-circuit impedance with that winding considered as the primary and the other short-circuited.

It is shown in Sec. 2, that in a branched circuit the current in each branch will be inversely proportional to the impedance of the branch. Since the effects of the primary and the secondary resistance and the magnetic leakage of the transformer may be represented by a simple impedance, the rule of branch circuits will also apply to parallel operation of transformers. In actual calculations the problem is usually to determine how a given number of transformers will divide a load of given kv-a. and power-factor. It will be found convenient in most cases, instead of using actual impedances or admittances, to use the ohmic and reactance drops expressed as fractions of the secondary voltage. Admittances derived from these are proportional to the actual admittance.

**128. Formulas.** Let the kv-a. rating of the transformers be $P_1$, $P_2$, $P_3$, etc., and let the impedance volts of each, expressed as a fraction of the rated voltage, be $(c_1+jd_1)$, $(c_2+jd_2)$, $(c_3+jd_3)$, etc., respectively, then the admittances $(g_1-jb_1)$, $(g_2-jb_2)$, $(g_3-jb_3)$, etc., will have the following values;

$$\left.\begin{aligned} g_1&=\left(\frac{c_1}{c_1^2+d_1^2}\right)\cdot\left(\frac{P_1}{P_1+P_2+P_3+}\right);\ b_1=\left(\frac{d_1}{c_1^2+d_1^2}\right)\cdot\left(\frac{P_1}{P_1+P_2+P_3+}\right)\\ g_2&=\left(\frac{c_2}{c_2^2+d_2^2}\right)\cdot\left(\frac{P_2}{P_1+P_2+P_3+}\right);\ b_2=\left(\frac{d_2}{c_2^2+d_2^2}\right)\cdot\left(\frac{P_2}{P_1+P_2+P_3+}\right)\\ g_3&=\left(\frac{c_3}{c_3^2+d_3^2}\right)\cdot\left(\frac{P_3}{P_1+P_2+P_3+}\right);\ b_3=\left(\frac{d_3}{c_3^2+d_3^2}\right)\cdot\left(\frac{P_3}{P_1+P_2+P_3+}\right)\end{aligned}\right\}\quad(39)$$

Digitized by Google

The joint admittance $Y$ is equal to the sum of all the admittances, or

$$Y = g - jb = g_1 + g_2 + g_3 + \ldots - j(b_1 + b_2 + b_3 + \ldots) \qquad (40)$$

The loads taken by the first, second, and third transformers expressed as fractions of the total kv-a. are respectively

$$\frac{\sqrt{g_1^2 + b_1^2}}{\sqrt{g^2 + b^2}}, \qquad \frac{\sqrt{g_2^2 + b_2^2}}{\sqrt{g^2 + b^2}}, \qquad \frac{\sqrt{g_3^2 + b_3^2}}{\sqrt{g^2 + b^2}} \qquad (41)$$

The power-factor of the load supplied by the transformers when the power-factor of the combined load is $\cos\alpha$ are respectively

$$\cos(\alpha + \theta_1 - \theta), \cos(\alpha + \theta_2 - \theta), \cos(\alpha + \theta_3 - \theta) \qquad (42)$$

where $\theta$, $\theta_1$ and $\theta_2$ are given by

$$\theta = \tan^{-1}\frac{b}{g} \qquad \theta_1 = \tan^{-1}\frac{b_1}{g_1} \qquad \theta_2 = \tan^{-1}\frac{b_2}{g_2}, \text{ etc.} \qquad (43)$$

**129. When the transformation ratios of two transformers are slightly different** they may be operated in multiple, without incurring much trouble. The currents $I_1$ and $I_2$ taken by the two transformers will depend upon the transformation ratios $m_1$ and $m_2$, the two transformer impedances $Z_1$ and $Z_2$ and the load impedance $Z_0$. The following formulas may be readily used by those familiar with complex imaginary quantities:

$$\left.\begin{aligned} \dot{I}_1 &= \frac{m_1\dot{Z}_2 + (m_1 - m_2)\dot{Z}_0}{\dot{Z}_1\dot{Z}_2 + \dot{Z}_0(\dot{Z}_1 + \dot{Z}_2)}\dot{V}_0 \\ \dot{I}_2 &= \frac{m_2\dot{Z}_1 - (m_1 - m_2)\dot{Z}_0}{\dot{Z}_1\dot{Z}_2 + \dot{Z}_0(\dot{Z}_1 + \dot{Z}_2)}\dot{V}_0 \end{aligned}\right\} \qquad (44)$$

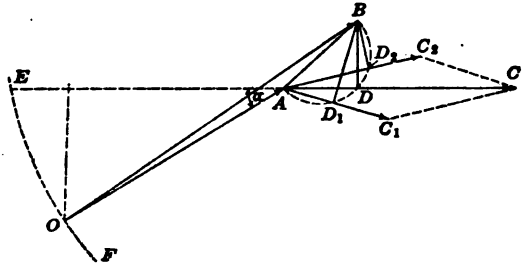

FIG. 21.—Vector diagram of two transformers operating in multiple.

**130. Compensation for differences in impedance** may be made by adding external reactance and resistance to the transformers whose reactance and resistance are too low. The amount to be added in each case is obviously that which will make the percentage value of the reactance drop and the ohmic drop, at the rated currents, the same in all transformers. **Where the ratio is different**, compensation by external reactances cannot be used, but resort must be had to balance coils or auto-transformers. This case will be dealt with under auto-transformers (Par. **173**). Auto-transformers may be used for producing proper distribution of load in all cases.

**131. Explanation of vector diagram, Fig. 21, for multiple operation.** In the above diagram $AB$ is taken of any arbitrary length to represent the combined impedance drop. $AD_1$ and $AD_2$ are each taken the same

Digitized by Google

fraction of $AB$ that the resistance drops of the respective transformers bear to their impedance drops. $AC_1$ is taken equal to the current that will produce the drop $AD_1$ in one transformer, and $AC_2$ is taken equal to the current that will produce the drop $AD_2$ in the other transformer. The resultant $AC$ is the combined current. The corresponding combined resistance drop is $AD$. The line $AC$ will then represent the combined load current on a certain scale, and $AC_1$ and $AC_2$ will represent the currents in the respective transformers, in magnitude and phase, on the same scale. Since the currents are known, the value of the impedance drop is known, and therefore the scale on which $AB$ represents the impedance drop is known also: we may take a certain length to represent the magnitude of the secondary open-circuit voltage on the same scale, and with $B$ as a centre strike an arc $EOF$; then, extending $CA$ to $E$, draw $AO$, making the angle $\alpha$ with $AE$, where $\cos\alpha$ is the power-factor of the load. $OA$ represents the secondary terminal voltage and $OB$ represents the secondary open-circuit voltage, or approximately the primary e.m.f. multiplied by the ratio of transformation, and with phase reversed.

## POLYPHASE TRANSFORMATIONS

**132. General considerations. Polyphase systems may be classified as symmetrical and unsymmetrical.** A symmetrical system may be defined as follows: if the system be $n$-phase, it will then consist of $n$ e.m.fs. of equal intensity differing from each other in phase by $\frac{1}{n}$th of a period. If $\dot{E}_1 = E_1 e^{j\omega t}$ is one of the e.m.fs. and if 1, $\alpha_1$, $\alpha_2$, $\alpha_{n-1}$ are the $n$ roots of the equation $x^n - 1 = 0$, we may write the $n$ e.m.fs. symbolically as follows:

$$\dot{E}_1 = \dot{E}_1, \quad \dot{E}_2 = \alpha_1 \dot{E}_1, \quad \dot{E}_3 = \alpha_2 \dot{E}_1, \quad \dot{E}_n = \alpha_{n-1} \dot{E}_1 \tag{45}$$

In such a system we shall have

$$\dot{E}_1 + \dot{E}_2 + \dot{E}_3 + \ldots + \dot{E}_n = 0 \tag{46}$$

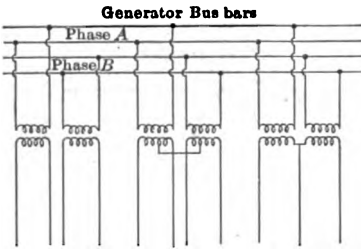

FIG. 22.—Two-phase systems.

and the **rules pertaining to branched alternating-current circuits** will also hold true for all polyphase circuits, viz.,

(a) The vector sum of all currents flowing toward a common point is zero.

(b) The vector sum of the electromotive forces taken round any closed circuit is zero, the effect of resistance and reactance being considered as counter e.m.fs.

The directions in the windings of the transformers which are taken as positive must be maintained consistently in the vector diagram, or symbolic representation of the electromotive force.

**133. Two-phase to two-phase transformation.** The usual transformation is effected by transforming each phase independently by means of a transformer; the four secondary leads are independent, forming the terminals of a four-wire non-interlinked two-phase system. If the middle points of the secondary bindings be connected together the four-wire symmetrical interlinked two-phase system is obtained. If two ends of the secondary winding be connected together the result is the two-phase three-wire system which is an unsymmetrical interlinked polyphase system and therefore not suitable for long distance transmission. In this system the e.m.f. between the other two ends of the windings is $\sqrt{2}$ times the e.m.f. across the windings. Fig. (22) illustrates these systems.

Digitized by Google

**134. Two-phase to three-phase transformation.** If in the interlinked two-phase system the middle point of one winding be connected to a point on the other winding 86.6 per cent. of the total number of turns from one end, this end of one secondary winding and the terminals of the other secondary winding will form the three terminals of a symmetrical system. The four secondary terminals form a two-phase unsymmetrical interlinked system (Fig. 23). The three-phase connection is known as the Scott Connection (Fig. 25). Balanced three-phase currents in this system will produce balanced two-phase currents in the primary winding.

**135. Three-phase to two-phase transformation.** If the primary winding of the two transformers be connected in the manner described in the preceding paragraph and a balanced three-phase e.m.f. be impressed on the three wires, the two secondary e.m.fs. will be in two-phase relation (Fig. 25).

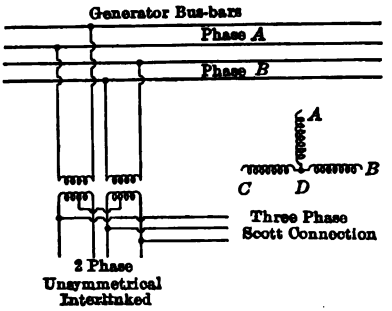

FIG. 23.—Evolution of Scott-connection from interlinked two-phase connection.

**136. Formulas for Scott two-phase to three-phase and three-phase to two-phase transformations at any load.** Four impedances are involved in the operation of this connection (Fig. 23), viz., the impedances of AD and CB with their primaries short-circuited; the impedance of CD with the primary of that transformer short-circuited; and the impedance obtained by connecting $C$ and $B$ together and circulating current through this winding, connected in this manner.

Designating these four impedances by $\dot{Z}_1$ $\dot{Z}_2$ $\dot{Z}_3\dot{Z}_4$, the following relation exists between the last three impedances:

$$\dot{Z}_2 = 4(\dot{Z}_3 - \dot{Z}_4) \tag{47}$$

Let the three-phase currents in the lines $A$, $B$ and $C$ be $\dot{I}_A$ $\dot{I}_B$ and $\dot{I}_C$, and designate the voltage across these phases by $\dot{E}_{AB}$ $\dot{E}_{BC}$ and $\dot{E}_{CA}$: let the primary of $AD$ have a voltage $E_1$ and the primary of $CB$ a voltage $E$. and let the ratios be $m_1$ and $m_2$; we shall have, since $\dot{I}_A$ $\dot{I}_B$ and $\dot{I}_C$ meet at a point, the relationship

$$\dot{I}_A + \dot{I}_B + \dot{I}_C = 0 \tag{48}$$

The expressions for the three-phase e.m.fs. in terms of the line currents and the two-phase e.m.fs. are

$$\left.\begin{aligned} \dot{E}_{AB} &= m_1\dot{E}_1 + \frac{m_2}{2}\dot{E}_2 + \dot{I}_A(\dot{Z}_1 + \dot{Z}_4) + (\dot{I}_C - \dot{I}_B)\frac{\dot{Z}_2}{4} \\ \dot{E}_{BC} &= -m_2\dot{E}_2 - (\dot{I}_C - \dot{I}_B)\frac{\dot{Z}_2}{2} \\ \dot{E}_{CA} &= -m_1\dot{E}_1 + \frac{m_2}{2}\dot{E}_2 - \dot{I}_A(\dot{Z}_1 + \dot{Z}_4) + (\dot{I}_C - \dot{I}_B)\frac{\dot{Z}_2}{4} \end{aligned}\right\} \tag{49}$$

By substituting from the relations

$$\dot{I}_1 = -m_1\dot{I}_A, \quad \dot{I}_2 = -\frac{m_2}{2}(\dot{I}_C - \dot{I}_B) \tag{50}$$

Digitized by Google

where $\dot{I}_1$ and $\dot{I}_2$ are the two-phase currents, the corresponding relations for three-phase to two-phase transformation are obtained.
When the currents $\dot{I}_A$, $\dot{I}_B$ and $\dot{I}_C$ are balanced,

$$\dot{I}_C - \dot{I}_B = j2\left(\frac{m_1}{m_2}\right)\dot{I}_A \tag{51}$$

and therefore in order that the three-phase e.m.f. may be balanced independently of the load,

$$\dot{Z}_2 = \left(\dot{Z}_1 + \dot{Z}_4\right)\left(\frac{m_2}{m_1}\right)^2 \tag{52}$$

$$\left.\begin{aligned} \text{or } r_2 &= (r_1 + r_4)\left(\frac{m_2}{m_1}\right)^2 \\ \text{and } x_2 &= (x_1 + x_4)\left(\frac{m_2}{m_1}\right)^2 \end{aligned}\right\} \tag{53}$$

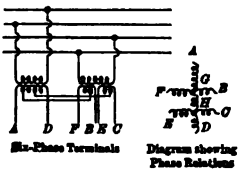

FIG. 24.—Two-phase to six-phase transformation.

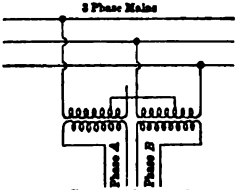

FIG. 25.—Scott three-phase to two-phase transformation.

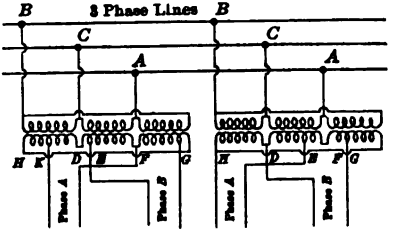
The necessary adjustment must be made to the two-phase side of the bank of transformers. As a general rule no compensation is needed in practical work, as the unbalancing due to the transformer is trifling compared with that due to other causes. The ratio $m_1/m_2$ for symmetrical two-phase to three-phase transformation is $\sqrt{3}/2$ so that $(m_2/m_1)^2$ is 1.33.

**137. Two-phase to six-phase transformation.** This transformation may be accomplished by using two Scott-connected banks of transformers, but a more satisfactory method is that shown in Fig. 24 in which two transformers are used. Referring to Fig. 24, *FB* and *EC* represent two secondary windings of one transformer, supplied by one phase; *AD* represents the secondary of the other transformer supplied by the other phase. The currents in *GA*, *GB*, *HC*, *HD*, *HE*, and *GF* are the six-phase line currents. The current in *GH*, when the load is balanced, is equal to twice that in *GA*, *GB*, etc. The magnitude of the voltage that must be developed in *FB* is $\sqrt{3}/2$ times that in *AD*. *AG* and *HD* contain one-fourth the number of turns that are in *AD*.



Taylor Connection 3 Phase to 2 Phase with 3 Transformers

3 Phase to 2 Phase with 3 Transformers
FIG. 27.

FIGS. 26 and 27.—Three-phase connections using three transformers.

**138. Three-phase to two-phase transformation with three transformers.** These methods of transformation offer some advantages in small installations where the cost of a spare unit is prohibitive, and it is desired to provide against the possibility of complete interruption of service due to

Digitized by Google

the loss of one unit of a bank. They also are useful in installations where it is the intention at a later period to change over from two phase to three phase and it is desired to have standard three-phase connections. That shown in Fig. 26 is known as the Taylor connection. Another connection of equal practicability is that shown in Fig. 27.

**139. The connections discussed above (Fig. 24 to Fig. 30) when supplying a balanced load in one system will produce a balanced load in the other system.** There are numerous connections to effect these transformations, however, which have not this advantage.

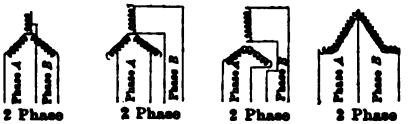

FIG. 28.—Three-phase to two-phase transformation systems.

They are not of sufficient importance to be dealt with in detail, but Fig. 28 illustrates a few of the most important of them.

**140. Three-phase to three-phase transformations.** The two most commonly used are illustrated in Fig. 29 and are usually designated delta connection and star connection; these connections are also referred to as mesh and Y-connections, respectively. See Par. 141. The relative merits of these two connections, or their combinations have, in the past, been the subject of a great deal of controversy; and even to-day, when their respective fields are well understood, a special prejudice in favor of one or the other sometimes appears.

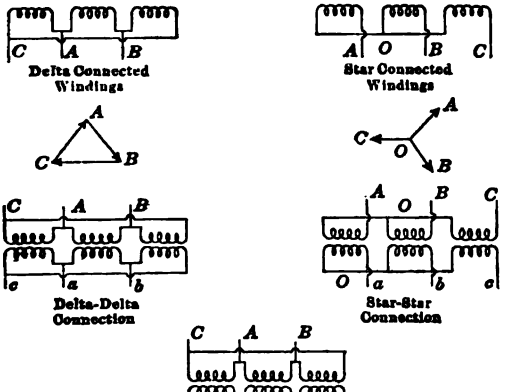

FIG. 29.—Standard three-phase to three-phase transformation systems.

**141. Discussion of star and delta connections.** For high transmission voltages the star connection is most desirable because the windings are made up of large conductors and are therefore stronger; the average stress on the insulation is less with the star connection, and the insulation between coils and layers, which is subjected to lower stresses, is also stronger on account of the greater mechanical strength of the coils. The only advantage possessed by the delta connection is that in case one transformer of a bank becomes inoperative, it may be cut out and the other two be used in "open delta" or "V"-connection to supply energy to the lines at a reduced rating. This advantage is of little value where spare units are available, as is the case in large installations.

**142. Star-star connection.** This arrangement is not generally adaptable for high-voltage transmission, for the following reasons. The arrange-

Digitized by Google

ment of the windings is such that the third-harmonic components of the exciting currents of the three transformers cannot flow therein, consequently a third-harmonic component appears in the wave-form of each e.m.f. between the neutral and line. Since the impressed e.m.f. between any two terminals cannot have a third-harmonic component, and since this e.m.f. must be equal to the vector difference of the e.m.fs. between neutral and the two terminals across which the e.m.f. is impressed, these third-harmonic components in the two e.m.fs. from $O$ to $A$ and from $O$ to $B$ (Fig. 29) must be equal and in phase. The same statement applies to the third harmonic of the e.m.f. between $O$ and $C$. There is therefore in each of the e.m.fs. $OA$, $OC$ and $OB$ a third-harmonic component of a value depending on the saturation of the core, and having exactly the same time phase. This triple frequency e.m.f. while not in itself serious, becomes so if the neutral of the secondary windings be grounded for then it sets up a triple frequency charging current through ground which interferes with neighboring telephone circuits.

**143. Another defect of this connection** (Par. 142) is instability of the neutral point which renders it unsuitable for four-wire three-phase distribution; furthermore if one transformer becomes short-circuited an overvoltage of 73 per cent. is impressed on the remaining two transformers. This defect may be overcome by connecting the primary neutral point to that of the generator, but this will not generally permit grounding the secondary neutral point because there is usually a third harmonic in the generator wave between neutral and ground.

**144. There are several ways in which the triple-frequency pulsation in the secondary may be removed.** One of them is to **interconnect the secondaries** of the three transformers as shown in Fig. 34. Another method is to provide a small delta winding for the purpose of supplying the necessary triple-harmonic component of the exciting current; this action of the delta connection in combination with the star is discussed under delta-star connections, Par. **148.** All of these schemes add to the cost, and more than counter-balance any gain that might be derived from using this (star-to-star) connection.

**145. In star-star connected three-phase core-type transformers** the third harmonic component of the e.m.f. between neutral and lines does not occur on account of the mutual inductance between phases.

**146. Delta-delta connection.** This connection is widely used. Each transformer has its exciting current directly supplied by the generator, so that there is no e.m.f. wave distortion. The load taken by each transformer in this connection will depend upon its impedance, so that transformers of different characteristics should not in general be connected together to form a delta-connected bank. If $\dot{I}_A \dot{I}_B$ and $\dot{I}_C$ are the secondary line currents and $\dot{I}_{AB} \dot{I}_{BC}$ and $\dot{I}_{CA}$ are the currents in the transformer secondaries, Fig. 29, and $Z_1, Z_2, Z_3$ are the impedances of the different transformers we shall have the following relations:

$$\left.\begin{aligned} \dot{I}_{AB} &= \frac{Z_2\dot{I}_B - Z_3\dot{I}_A}{Z_1+Z_2+Z_3} \\ \dot{I}_{BC} &= \frac{Z_3\dot{I}_C - Z_1\dot{I}_B}{Z_1+Z_2+Z_3} \\ \dot{I}_{CA} &= \frac{Z_1\dot{I}_A - Z_2\dot{I}_C}{Z_1+Z_2+Z_3} \end{aligned}\right\} \quad (54)$$

**147. Delta-star and star-delta connections.** These methods of connecting a bank of transformers are the best for **high-voltage transmission,** the delta-star connection being used for stepping-up and the star-delta for stepping-down. When the voltage is stepped-up with a delta-star connection, the neutral of the star may be grounded without introducing any trouble, because the third-harmonic e.m.f. and its multiples, which are the

Digitized by Google

chief source of trouble in three-phase lines, are thereby almost completely eliminated from the e.m.f. between the neutral point and the three secondary terminals.

**148. The actions which take place in the delta-connected secondaries of the star-delta** step-down transformers are of importance. The necessary triple-harmonic components of the exciting currents cannot flow in the primary windings because they are star connected, and a third-harmonic component in the primary e.m.fs. between phase lines and neutral cannot exist on account of the secondary delta connection; but instead a triple-harmonic current is set up around the delta which effectively supplies the place of the missing third component of the exciting current in the primary. This current is of the same order of magnitude as the true third-harmonic component of the exciting current.

**149. When the wave-form of the e.m.f. between phase lines is distorted by harmonics,** the wave-form of the secondary when stepped-down by a bank of star-delta connected transformers will not be the same as that of the e.m.f. between lines of the primary. It will be found that harmonics which peak the e.m.f. between phase lines will cause the e.m.f. between line and neutral, impressed on the transformer, to be flattened—and *vice versa*. If the e.m.fs. between phase lines are sine-waves, the e.m.fs. between lines and neutral will also be sine-waves and will have values equal to 0.577 of the line e.m.fs. and will lead one of them in time phase by 30 deg: These relations will also be true of the effective values when star-delta connections are used, no matter how badly the wave form of primary e.m.f. may be distorted, but the relations will not hold for maximum values.

**150. Formulas for currents in delta-star and star-delta connected transformers.** In the delta-star connection the line current is equal to the secondary current and the primary current is obtained by multiplying it by the ratio of transformation (Par. 7). The regulation may then be calculated in the same way as in single-phase transformers. In the star-delta connection, considering the secondary windings, the respective currents in the windings being $I_{ab}$, $I_{bc}$, $I_{ca}$ and the currents in the terminals being $I_a$, $I_b$ and $I_c$ we have the relations

$$I_{ab} = \tfrac{1}{3}(I_b - I_a),\ I_{bc} = \tfrac{1}{3}(I_c - I_b),\ I_{ca} = \tfrac{1}{3}(I_a - I_c) \qquad (55)$$

The primary impressed e.m.fs. are related, as follows:

$$E_{AB} = E_{OB} - E_{OA},\quad E_{BC} = E_{OC} - E_{OB},\quad E_{CA} = E_{OA} - E_{OC} \qquad (56)$$

Assuming unity ratio of transformation in windings and transformer impedances, $Z_1$, $Z_2$, $Z_3$ the secondary voltages $E_{ab}$, $E_{bc}$, $E_{ca}$ are related to the corresponding primary voltages as follows:

$$\left.\begin{aligned} E_{ab} &= \tfrac{1}{3}\left\{E_{BC} - E_{AB} - \frac{2Z_1}{3}(I_b - I_a) + \frac{Z_2}{3}(I_c - I_b) + \frac{Z_3}{3}(I_a - I_c)\right\} \\ E_{bc} &= \tfrac{1}{3}\left\{E_{CA} - E_{BC} - \frac{2Z_2}{3}(I_c - I_b) + \frac{Z_3}{3}(I_a - I_c) + \frac{Z_1}{3}(I_b - I_a)\right\} \\ E_{ca} &= \tfrac{1}{3}\left\{E_{AB} - E_{CA} - \frac{2Z_3}{3}(I_a - I_c) + \frac{Z_1}{3}(I_b - I_a) + \frac{Z_2}{3}(I_c - I_b)\right\} \end{aligned}\right\} \qquad (57)$$

These equations become very simple when $Z_1$, $Z_2$ and $Z_3$ are equal. For this condition the following relations also hold:

$$E_{OA} = \tfrac{1}{3}(E_{CA} - E_{AB}),\ E_{OB} = \tfrac{1}{3}(E_{AB} - E_{BC}),\ E_{OC} = \tfrac{1}{3}(E_{BC} - E_{CA}) \qquad (58)$$

**151. Unsymmetrical three-phase to three-phase connections; "V"- and "T"-connection (Fig. 30).** The most commonly used of the unsymmetrical connections is the "*V*"-connection, not because it has any inherent advantage over the others, but for the reason that when it is desired to increase the capacity of the bank a third transformer may be added and a delta-delta connection obtained.

Digitized by Google

**152. Formulas for "V"-connected transformers.** Taking $Z$ as the transformer impedance and $Z_0$ as that of the load on each phase, and $\dot{E}_A$, $\dot{E}_B$ and $\dot{E}_C$ as the primary star-e.m.fs., and assuming the ratio of transformation to be unity, the primary currents will be

$$\left.\begin{aligned} \dot{I}_{AB} &= \frac{\dot{E}_B}{Z + \frac{Z_0}{3}} + \frac{\dot{E}_C}{Z + \frac{Z_0}{3}} \\ \dot{I}_{BC} &= -\frac{\dot{E}_B}{Z + \frac{Z_0}{3}} - \frac{\dot{E}_A}{Z + \frac{Z_0}{3}} \end{aligned}\right\} \quad (59)$$

If we place in the primary, at $B$, a reactance equal to $\frac{1}{2}Z$ (Fig. 30), the ratio being assumed to be unity, we shall have

$$\left.\begin{aligned} \dot{I}_{AB} &= \frac{\dot{E}_B + \dot{E}_C}{Z + \frac{Z_0}{3}} = -\frac{\dot{E}_A}{Z + \frac{Z_0}{3}} \\ \dot{I}_{BC} &= -\frac{\dot{E}_B + \dot{E}_A}{Z + \frac{Z_0}{3}} = \frac{\dot{E}_C}{Z + \frac{Z_0}{3}} \end{aligned}\right\} \quad (60)$$

The connection is now balanced and gives exactly the same secondary e.m.fs. at a load of any impedance as a bank of delta-connected transformers having equal impedances of value $3Z$.

**153. The "T"-connection is economical in first cost.** It consists of two transformers, one of which has both its primary and secondary wind-

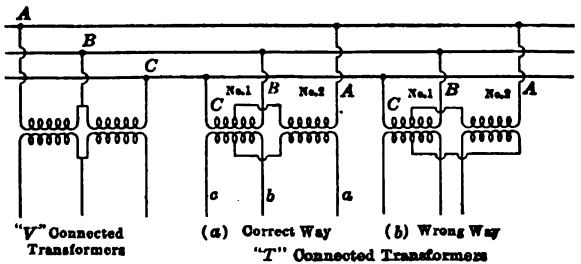

FIG. 30.—Unsymmetrical three-phase to three-phase transformations.

ings designed for 87 per cent. of the three-phase voltages; the other is designed for the full voltage, and both primary and secondary windings are provided with taps at the middle points. The transformers are connected as shown in Fig. 30.

**154. Formulas for "T"-connected transformers.** Assuming unit ratio the currents in the primary winding will be equal in magnitude and opposite in time-phase to the line currents in the secondary. If $Z_1$ is the impedance of the 87 per cent. transformer and $Z_2$ is the impedance of one-half of the primary of the other transformer, with the corresponding half of the secondary short-circuited, and if $\dot{E}_{AB}$, $\dot{E}_{BC}$ and $\dot{E}_{CA}$ are the primary impressed e.m.fs., the secondary e.m.fs. will be

Digitized by Google

$$\begin{aligned}\dot{E}_{ab} &= -\{\dot{E}_{AB} + \dot{Z}_2\dot{I}_A - \dot{Z}_3\dot{I}_B\}\\ \dot{E}_{bc} &= -\{\dot{E}_{BC} + \dot{Z}_3(\dot{I}_B - \dot{I}_C)\}\\ \dot{E}_{ca} &= -\{\dot{E}_{CA} + \dot{Z}_3\dot{I}_C - \dot{Z}_1\dot{I}_A\}\end{aligned} \qquad (61)$$

The condition which must be filled by the impedances so that there shall be no unbalancing, is that $Z_3$ must be equal to $Z_1$. If this condition does not exist, additional impedance may be introduced so as to produce the desired equality.

**155. In the design of transformers for "T"-connections,** that one which has the tap at the middle point of the winding, should have the two halves of the primary and secondary windings, which carry currents of opposite time-phase, well interlaced with each other. The **relative polarity** of the two transformers plays an important rôle in the operation of this connection. For transformers of like polarity the proper connection is that shown at "*a*" in Fig. 30. That shown at "*b*" in Fig. 30, is incorrect and will cause poor regulation, because the currents that are in phase in the primary and secondary windings of the transformer No. 1 flow in the halves that are not interlaced and therefore encounter high impedance. The transformer No. 1 could be designed so as to operate equally well with either connection, but this would involve interlacing the primary and secondary windings in a manner that would be extremely costly.

**156. Polarity in polyphase transformation.** It is important to know the polarity of the transformers in a bank connected for polyphase transformation, when parallel operation with other banks of transformers of different manufacture is to be considered.

**157. Certain polyphase connections cannot be operated in multiple with certain others,** as for instance star-delta or delta-star connection with star-star or delta-delta. In three-phase transformers, when the polarity of one is reversed from that of another, it may be difficult to get at the connections to change them; care should therefore be taken in designing such transformers for parallel operation with others. (This problem and that of polarity is discussed in detail under "Installation, Care and Operation of Transformers," Par. **232** to Par. **237**.)

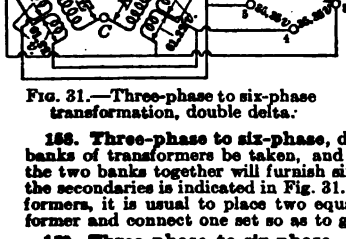

FIG. 31.—Three-phase to six-phase transformation, double delta.

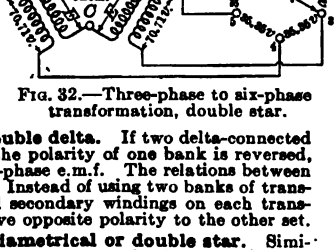

FIG. 32.—Three-phase to six-phase transformation, double star.

**158. Three-phase to six-phase, double delta.** If two delta-connected banks of transformers be taken, and the polarity of one bank is reversed, the two banks together will furnish six-phase e.m.f. The relations between the secondaries is indicated in Fig. 31. Instead of using two banks of transformers, it is usual to place two equal secondary windings on each transformer and connect one set so as to give opposite polarity to the other set.

**159. Three-phase to six-phase, diametrical or double star.** Similarly, if the two sets be connected in star, one set having its windings reversely connected with respect to the other set (Fig. 32), we shall have six-phase e.m.fs. It is not necessary in this transformation when the neutral connection is required, to have two secondary windings; instead a middle tap may be brought out, all the middle taps of the three transformers being connected together to form the neutral.

**160. Three-phase to six-phase, double tee.** A method of obtaining six-phase currents from a three-phase system, by means of a double tee or "T" connection, is shown in Fig. 33.

Digitized by Google

**161. The interconnected-star connection** shown in Fig. 34 is used in connection with direct-current three-wire distributing systems. This connection permits continuous current in the neutral wire to flow through the transformers without magnetising them.

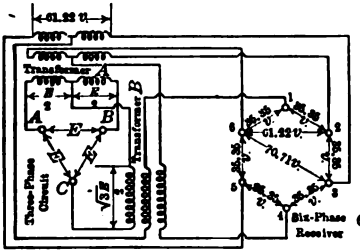

FIG. 33.—Three-phase to six-phase transformation, double tee.

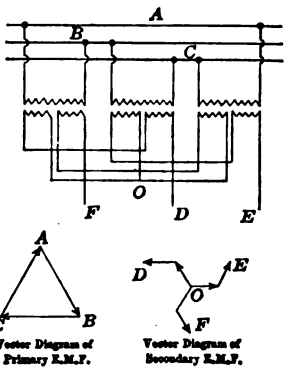

FIG. 34.—Interconnected star connection.

## CONSTANT-CURRENT TRANSFORMERS

**162. The constant-current transformer depends for its regulation on the force of repulsion between the primary and the secondary coils** which carry currents that are in opposite time-phase. Referring to Fig. 35 and Fig. 4, as the load impedance decreases, the current will first increase, if the quantities $(L_1 - M)$ and $(L_2 - M)$ remain constant, but if the latter increases in the right proportion the current will remain constant. As the load impedance $r_0 + jx_0$ is decreased, the total reactance in the secondary circuit will decrease, and the short-circuit reactance of the primary circuit will increase a corresponding amount. The ratio of current transformation will therefore remain practically constant throughout the range. The apparatus may thus be considered as a device to maintain a constant effective primary impedance, independent of the load. The short-circuit impedance with full-load coil separation should be as low as consistent with a reasonable cost or satisfactory operation, but with no-load separation it should be high enough to limit the current to its normal value. Sometimes the transformer is designed with regulation to take care of the cutting out of a portion, only of the load impedance, in which case the short-circuit impedance voltage of the primary circuit for normal current will be less than the primary impressed voltage.

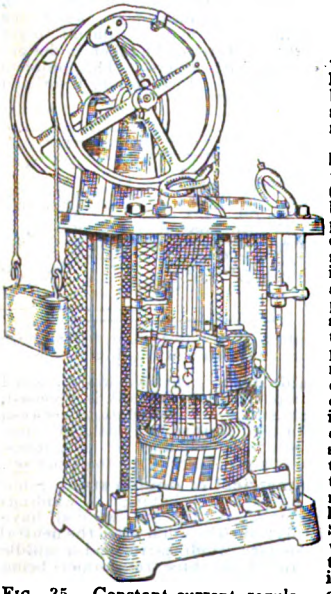

FIG. 35.—Constant-current regulator transformer.

**163. In the design of constant-current transformers for tungsten lamps,** requiring a given total number of kv-a., a smaller transformer is required than that for arc lamps of the same kv-a. rating, on account of the low power-factor of the arc lamp, and, a current regulator for use with a mercury-vapor rectifier to supply direct-current arc lamps will require a still larger transformer. The procedure for obtaining the exact kv-a. of transformer required consists in working out from the characteristics of the load and the assumed characteristics of the transformer the open-circuit secondary voltage; the product of this and the required secondary current is the kv-a. rating. The design may then be made along the same general lines as for power transformers, except that the short dimension of the coil space will be determined from the effective short-circuit impedance of the regulator with full-load coil separation, while the long dimension will be determined by the no-load short-circuit impedance required, and the length of the coils. The value of the product $A_1A_2$ (Par. **21**) may be varied and the cheapest design obtained in each case, the loss in watts per sq. in. of surface being in each case such as will produce the same rise of temperature above the cooling medium. In this manner the most suitable design may be obtained.

**164. Methods of cooling.** Generally, in constant-current regulators for tungsten lamps and alternating-current arc lamps, natural air cooling is used, but this is chiefly on account of the fact that the kv-a. ratings required are quite low. For higher ratings, above 100 kv-a., the regulator is immersed in oil, and in some cases is cooled by water.

**165. Mechanical design and adjustments.** Usually the design consists of one stationary coil and a moving coil, the latter being generally the primary coil. Sometimes both coils are movable, in which case they may be arranged to counter-balance each other by means of two wheels or lever arms arranged as shown in Fig. 58. When there is one movable coil only, it must be counter-weighted, but where both coils are movable a counter-weight will not be required, although in adjusting it will be found necessary to add weight to the upper coil to obtain the proper balance against the repulsive force. Besides these adjusting weights, adjustment may be found necessary in the relative lengths of the lever arms at different positions, or in case wheels are used, it may be found necessary to add weight at different points of the rim. A dashpot should be provided to damp the motion of the coils, otherwise the instability of the arc lamps would cause "pumping" of the regulator and flickering of the lamps. The mechanical design should permit of easy and accurate adjustment. In addition to the nominal voltage, the primaries are often wound for voltages 10 per cent. above and below the nominal value.

**166. Types and characteristics.** The constant-current transformer does not admit of much variation in form, and therefore one general type is in use, which experience has shown to be most efficient. This type consists of either movable primary or secondary coil, or both may be movable, and a shell-type magnetic circuit which may have a rectangular or cruciform cross-section.

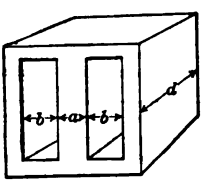

FIG. 36.—Magnetic circuit of constant current regulator.

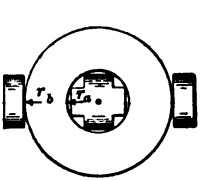

FIG. 37.—Cross-section of cruciform core of constant current regulator.

**167. Formulas for constant-current transformers.** The formulas for the effective primary inductance and repulsive force are given below: the symbols refer to the dimensions shown in Fig. 36 and Fig. 37. The inductance for a rectangular-core regulator is

$$L = \frac{4\pi CN^2}{10^9}\left\{\frac{5.08d}{b} + 129\left(\frac{\frac{1}{\pi}}{+\frac{2b}{a+b}}\right)^2\right\} \quad \text{(henrys)} \qquad (62)$$

Digitized by Google

The inductance for a cruciform-core regulator is

$$L = \frac{4\pi CN^2}{10^9}\left(\frac{7.6}{0.23 + \log\frac{r_a}{r_b}}\right) \quad \text{(henrys)} \quad (63)$$

For each case the repulsive force $F$ is

$$F = \tfrac{1}{2} I_1^2\left(\frac{100L}{4.45\times 2.54\times C}\right) \quad \text{(pounds)} \quad (64)$$

The value of $C$ is obtained by adding to the coil separation the insulation clearance between coils plus 0.45 times the length of each coil. All dimensions are to be measured in inches.

**168. Regulation, of constant-current transformers** for arc-lighting is usually guaranteed over a range from full load to no load. If properly adjusted, the current should be within 0.1 amp. of the normal value of current for any number of lamps between full load and no load.

**169. The satisfactory working of alternating-current arc lamps** demands a certain amount of reactance in the lamp circuit. This is provided in the transformer by its own effective reactance. The full-load operating power-factor of an alternating-current arc-lamp system seldom excells 70 per cent.; at small loads the power-factor is very much less. A table of efficiency and rating is given in Par. **171**.

**170. Constant-current regulators for series tungsten lamp lighting** are similar in design to the alternating-current series arc lamp constant-current transformer, except that the dashpot is omitted. Ratings and efficiencies are given in Par. **172**.

The above values of performance are based on constant-current transformers designed to operate on a 2,200-volt circuit; the number of lamps comprising the secondary load will depend upon their operating current and voltage.

## AUTO-TRANSFORMERS

**173. General principles.** The auto-transformer is nothing more than a transformer so connected that part of the load current is supplied by the primary current, and part by the secondary current. The relative amount supplied by each will depend upon the ratio of transformation. If the ratio of transformation is large, the current in the secondary will be large compared with that in the primary, and the proportion of the load current contributed by the primary current will be small; on the other hand, if the ratio of transformation approaches unity the primary current will be large compared with the secondary current, and therefore the primary current will supply the greater portion of the load. Fig. 38 illustrates the connections of a transformer for use as an auto-transformer, and gives also a physical conception of the current relations in the latter. The primary voltage is the difference between the voltage of the supply circuit and that of the secondary circuit. The load current is supplied from the primary and the secondary in approximately inverse proportion to the respective number of turns in their windings. Therefore, the lower the ratio of transformation, the smaller will be the transformer required to deliver a given load, and the more efficient will be the transformation. The method of connection may be modified from that shown in Fig. 38, but the principle is unchanged. As the load on the secondary is increased the primary voltage becomes greater, so that the regulation of an auto-transformer is very much better than when used as a simple transformer.

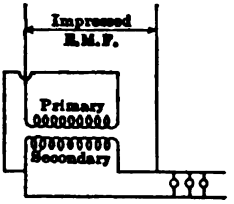

FIG. 38.—Transformer shown connected as an auto-transformer.

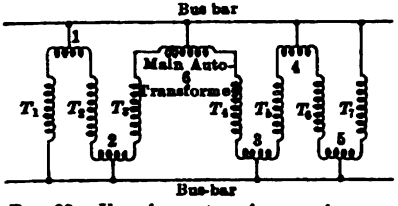

FIG. 39.—Use of auto-transformers for paralleling transformers.

**174. Types and characteristics.** Auto-transformers may be used for every purpose for which transformers are used, but there is little to be gained by using them for large ratios of transformation, and on high-voltage work their use requires a grounded system for the sake of safety in operation.

**175. Auto-transformers for power purposes** may be used instead of transformers to step-up or step-down the voltage of a grounded transmission line. Such an arrangement is found very convenient when supplying power to a grounded system from a grounded supply circuit. A good example of the use of auto-transformers for power purposes is afforded by the New York, New Haven and Hartford Railroad system, in which the 11,000-volt trolley circuit is supplied through auto-transformers at each section from the 22,000 volt-feeder circuits. Auto-transformers may also be used as a means of interlinking two systems of different voltages; the three-phase auto-transformer is commonly used for this purpose.

**176. Auto-transformers or balance coils** are often employed to obtain the middle wire, or neutral wire, of a three-wire alternating-current system. The size of balance coil used is ordinarily one that will take care of 25 per cent. unbalancing of the system.

**177. Auto-transformers or balance coils for three-wire direct-current systems.** The connection shown in Fig. 23 of Sec. 9 is sometimes used to obtain the neutral of a three-wire direct-current system.

Digitized by Google

**178. Auto-transformers for producing a proper division of the load between transformers operating in parallel.** There are several ways in which auto-transformers may be used for this purpose; one of these, by which a group of any number of transformers of one design may be connected so as to operate in multiple with a group of any number of transformers of another design, is illustrated by Fig. 39. The illustration shows only single-phase groups, but polyphase groups may be paralleled in a similar manner.

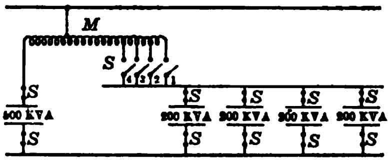

Fig. 40.—Use of auto-transformers for paralleling transformers.

Another method of paralleling two groups of transformers is illustrated in Fig. 40. In this method it is necessary to have an auto-transformer with a number of taps, so that the proper tap may be used for each combination of groups. When paralleling two transformers of unequal impedance drop at their rated currents, the voltage across the whole winding of the auto transformer will be

$$\sqrt{(I_1r_1 - I_2r_2)^2 + (I_1x_1 - I_2x_2)^2} \tag{64}$$

The winding should be designed to have the turns in each portion inversely proportional to the rated current of the transformer connected to it.

**179. The regulation of an auto-transformer** is illustrated most clearly by means of a vector diagram. Fig. 41 shows the vector diagram of a step-down auto-transformer. Fig. 42 shows that of a step-up auto-transformer. The construction is as follows: $OA$ is the primary counter e.m.f. $OB$ is equal to $OA$ multiplied by the ratio of transformation. The impedance drop $BE$, in the case of the step-down auto-transformer (Fig. 41) is equal to $(1-m)$ times the short-circuit impedance voltage of the auto-transformer considered as a transformer with the primary short-circuited, the secondary of the transformer being that portion of the winding which forms the secondary of the auto-transformer, the primary being the remaining portion, '$m$' being the ratio of transformation. In the vector diagram for the step-up auto-transformer (Fig. 42) the impedance drop $BE$ is equal to the short-circuit impedance of the secondary with the primary winding short-circuited, the secondary being that of the auto-transformer considered as a

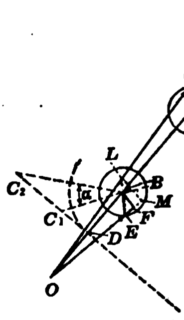

Fig. 41.—Step-down.

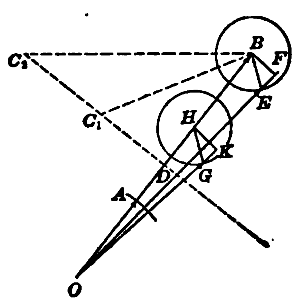

Fig. 42.—Step-up.

Figs. 41 and 42.—Vector diagrams of voltage relations in step-down and step-up auto-transformers.

Digitized by Google

transformer. In each case $OE$ is the secondary e.m.f. at 100 per cent. power-factor and $OG$ is the e.m.f. across the remaining portion of the winding. The triangle $HGK$ is equal to $BEF$. The vector diagrams, Fig. 41 and Fig. 42, show the regulation for a load of 100 per cent. power-factor; the loci for any load of any power-factor may be obtained by following the construction shown in Fig. 6, described under "General Theory," Par. 22.

180. **The cost of an auto-transformer** designed to deliver a given amount of power $P$, depends upon the ratio of transformation. The actual rate at which energy is transformed electromagnetically in the auto-transformer, is the true criterion of its cost; this rating may be conveniently referred to as the **equivalent transformer rating**, though it should be kept in mind that in the auto-transformer the insulation stresses may be different from those that occur in the transformer. If $m$ be the ratio of the low-tension e.m.f. to the high-tension e.m.f. of the auto-transformer at no load, the equivalent transformer rating will be $(1-m)P$, where $P$ is the auto-transformer rating. If $m=\frac{1}{2}$, the transformer rating of the auto-transformer is one-half its auto-transformer rating. If $m$ be very small, the two ratings approach equality; if $m$ be larger, the transformer rating is very small compared with the auto-transformer rating. The cost of the auto-transformer may thus be expressed in terms of a two-winding transformer with certain conditions of insulation stress to be considered. Since auto-transformers are most generally used on low-voltage circuits, the effect of the difference in insulation stress is usually negligible.

181. **Induction starters are auto-transformers** connected for operation on polyphase circuits, to reduce the voltage applied to an induction motor at starting. Usually a number of starting-points are provided, so that the same design may be used for different starting conditions.

## INSTRUMENT TRANSFORMERS

182. **Shunt-type (potential) transformers are used for many classes of work**, such as operating relays for voltage regulation and protection, operating recording instruments, power-factor meters, and switchboard instruments, including voltmeters and wattmeters. For accurate work a potential transformer should carry the load of one instrument only, and should be compensated for this load.

183. **In the design of shunt-type (potential) transformers** it is important to keep the weight of iron and the effective impedance as low as possible; therefore the insulating material used must be highly efficient as an insulator, and the coils must be so subdivided, wound, and insulated as to occupy the minimum amount of space. The induction must be fairly low, so as to avoid distortion of wave form due to the exciting current.

184. **Compensation for the effect of the load current and the exciting current** may be calculated from the equivalent circuit as discussed in Par. 19, under "General Theory." No definite rules can be laid; the best guide is a comparison between calculated values and test results.

185. **Shunt-type instrument transformers are manufactured to operate on all voltages**, up to 100,000 volts. For very high voltages the design of a reliable transformer of low cost becomes exceedingly difficult; the cost of the terminals alone is a very large item.

186. **Series-type (current) transformers.** It has been shown that in such transformers the effect of wave-form distortion of the secondary current on the accuracy of measurements is so small as to be undetectable, even with the most accurate instruments available. It follows that in considering any particular load the wave form of the secondary current may be assumed to be a sine-wave and the equivalent sine-wave value of the exciting current may be taken. It will be found convenient in practical work to consider the ratio as unity, and the primary current reversed in time phase so as to be nearly in phase with, instead of being nearly in opposition to, the secondary current, it being of course understood that the phase of one of them must be reversed in a transformer. Then, referring to Fig. 4 under "General Theory" (Par. 19 to Par. 22), we find that the induced voltage in the secondary voltage in the secondary circuit under load of impedance $Z_0 = R_0 + j\omega L_0$ is

$$\dot{I}_2\left[R_2 + R_0 + j\left\{(\omega[L_2 - M] + \omega L_0\right\}\right] \qquad (65)$$

Digitized by Google

The mean induction in the core will depend on this e.m.f. and may be found by means of Eq. 4. Let the angle of lag of the exciting current behind the induced e.m.f. be $\alpha$ and let its value considered with reference to the secondary winding be $I_m$; then if the angle of lead of the induced e.m.f. over $I_2$ be $\theta$, determined by the formula,

$$\tan\theta = \frac{\omega(L_2 - M) + \omega L_e}{R_2 + R_e} \tag{67}$$

we shall have

$$\dot{I}_1 = \dot{I}_2\left[\sqrt{1 + \left(\frac{I_m}{I_2}\right)^2 + 2\frac{I_m}{I_2}\cos(\theta - \alpha)}\right] e^{j\theta_1} \tag{68}$$

where $\theta$ and $\alpha$ are already defined, and the value of $\theta_1$ is found from the formula

$$\tan\theta_1 = \frac{\frac{I_m}{I_2}\sin(\theta - \alpha)}{1 + \frac{I_m}{I_2}\cos(\theta - \alpha)} \tag{69}$$

The quantity under the radical in Eq. 67 is the factor by which the ratio turns must be multiplied in order to get the ratio of transformation, and $\theta_1$ is the lead of the primary current over the secondary current.

**187. The important factors in the design of series (current) transformers** are the load impedance and the effective secondary impedance for these together determine the mean induction in the iron for a given secondary current. These factors being fixed the excellence of the design will depend on the quality of the iron and the care taken in building which should be such as to make $I_m$ as small as possible. Care should be taken in the mechanical design to avoid eddy currents in the end frames, and in the electrical design that in the endeavor to make the induction low by using a large number of turns this purpose is not defeated by the large increase in secondary reactance produced thereby.

**188. The effect of these factors and of different qualities of iron** may be studied by means of curves of ratio and phase displacement, such as that shown in Fig. 43 which was made by a method similar to those recommended by Crawford and Sharp, Agnew and others (see Sec. 3).

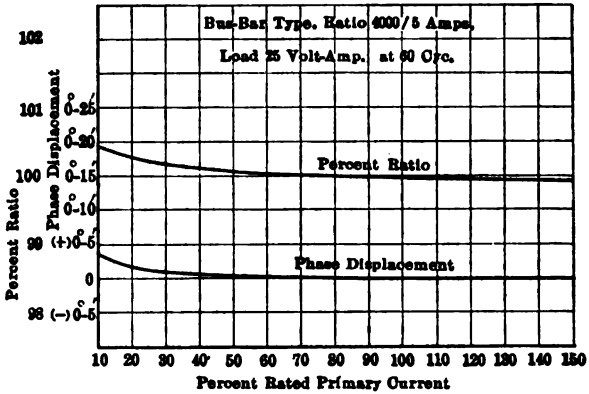

FIG. 43.—Calibration curve of a standard bus-bar type series transformer.

**189. Series (current) transformers for high-voltage circuits** are generally costly on account of the necessity of insulating them heavily and if they are oil-immersed they require in addition a high-voltage terminal.

Digitized by Google

A new design has been developed for high voltages which is less costly. It consists of a core which is wound with the secondary winding, while the primary winding is wound through a condenser lead which passes through the opening of the core.

**190. Correction factors for power measurements.** Errors introduced in measurements made with the use of series (current) and shunt (potential) transformers are usually negligible, if the power-factor of the load measured is high. On low power-factors the results will be inaccurate to an appreciable degree and the calibration curves of the transformers should be used in order to make the necessary corrections. If the power-factor of the load be cos $\alpha$ and the angle of lead of the secondary current of the series (current) transformer be $\theta_1$ and the angle of lead of the secondary e.m.f. of the shunt (potential) transformer be $\theta_2$, and if $\rho_1$ and $\rho_2$ are the corrections to be applied to their name-plate or nominal ratios as indicated on the correction curve (Fig. 43), and further if $E_2$ and $I_2$ are the observed values of the secondary e.m.f. of the shunt (potential) transformer and the secondary current of the series (current) transformer, respectively, then

$$\cos(\alpha - \theta_1 + \theta_2) = \frac{\text{wattmeter reading}}{E_2 I_2} \qquad (70)$$

The correct value for the power measured will then be obtained by multiplying the observed reading by the factor

$$\left[\frac{\cos\alpha}{\cos(\alpha - \theta_1 + \theta_2)}\right] \rho_1 \rho_2 \text{ multiplied by (product of nominal ratios)}$$

**191. Standard series (current) transformers** are designed to give a current of 5 amp. in the secondary winding with full-load current in the primary winding, and a load of 25 volt-amp. They are made for use on circuits from 2,200 volts up to 20,000 volts, air-cooled, and for primary currents of 5, 10, 15, 20, 30, 40, 50, 60, 75, 80, 100, 120, 200, 300 and 400 amp. Transformers designed to slip over a stud or cable which constitutes a one-turn winding, are made for primary currents from 600 amp. up to 3,000 amp. Series (current) transformers for higher voltages than 20,000 volts are usually oil-insulated.

**192. All instrument transformers should have their secondary windings grounded,** because a high potential may be induced in the secondary winding depending on the mean potential of the primary winding to ground and the ratio between the electrostatic capacity of the secondary winding to ground, and the electrostatic between primary and secondary windings. In addition to this in the case of series transformers precaution should be taken to see that the *secondary winding is short-circuited before an instrument is removed*, otherwise an excessive e.m.f. will be induced in the secondary winding due to the line current now becoming the magnetizing current of the transformer. This is true of all series (current) transformers, but the e.m.f. becomes particularly high in transformers designed for a high degree of accuracy, and in bus-bar type transformers for 1,000 amp. and above.

## TRANSFORMERS FOR MISCELLANEOUS USES

**193. Track transformers for operating signals** are small transformers similar in design to those used for sign lighting, hereafter described. The secondaries of the transformer are connected across the two rails of a track while the primaries are supplied from 110 volt feeders which are in turn supplied by small step-down transformers similar to standard lighting transformers from 60 cycles or 25 cycles 2,200- or 6,600-volt transmission lines.

**194. A line-drop compensator** is a device for obtaining with a voltmeter located in the generating or substation the voltage at the end of a line, or at some predetermined point, and consists essentially of a reactance and a resistance in series, which may be varied by means of taps. A current proportional to the line current is circulated through them by means of a series-type (current) transformer, and the secondary of a shunt-type (potential) transformer is connected to the proper point of one of them by means of a dial; the voltmeter or potential relay is connected between the remaining terminal of the shunt-type transformer, and the proper point of the other element of the compensation, by means of a dial. With a proper choice of current transformer and with proper connections and adjustment

Digitized by Google

of the dials the voltmeter or potential relay will indicate the voltage at the desired point of the feeder or line for any load.

**195. Theory of line-drop compensators.** Refer to Fig. 6 (under "General Theory"). The voltage at the station is represented by the secondary open-circuit voltage, and the voltage at the end of the line or centre of distribution is represented by the secondary full-load voltage; the reactance drop and the ohmic drop of the compensator are represented by the secondary short-circuit reactance drop and resistance drop, respectively.

**196. In order to obtain the highest accuracy with line-drop compensators,** it is necessary that the voltmeter operate on a small current compared with that passing through the compensator. Compensators for use with potential regulators, should be designed for larger currents than those for use with indicating instruments.

**197. Compensating transformers for neutralising inductive disturbances in telephone and telegraph lines.** Where telephone or telegraph circuits parallel an alternating-current traction system, high voltages may be induced in them due to electromagnetic induction from the railway system. To overcome this trouble, a number of extra pairs of wires are placed among the other telephone wires so that their mutual inductance to the railway circuits is the same as those of the regular telegraph or telephone wires. These extra wires are grounded at various points, and connected to the primary windings of a special transformer, so that the e.m.fs. induced in them magnetize the transformer in the same direction. The telephone or telegraph wires are then connected to secondary coils of this transformer, so that the induced e.m.f. of the transformer opposes and neutralizes the induced e.m.f. due to the railway system. Since the two wires of any pair encircle the core in the same direction, the secondary windings are practically non-inductive, as far as the telephone currents are concerned. The transformers are usually of the core-type construction and differ from ordinary transformers only in the large number of secondary coils and the manner in which they are wound so as to obtain freedom from cross talk.*

**198. Insulating transformers for telephone lines** are designed to protect both the telephone and the user from high voltages, due either to induction or accidental contact with a high-tension line. This device consists of a shunt transformer provided with a condenser across the primary terminals, the purpose of the condenser being to supply the greater portion of the magnetizing current of the transformer under normal operation. The secondary terminals are connected to the telephone in the usual way. Such transformers are usually built to stand a 25,000-volt test, for 1 min., between the windings, and between windings and case. A lightning arrester and special fuses are generally provided for the primary circuit. The secondary may be grounded if desired, or an insulated stool provided for the user to stand upon.

**199. Extra-high-voltage testing transformers.** Test voltages as high as 375,000 volts above ground potential are becoming common, such a test voltage requires a testing transformer equivalent in insulation strength to one designed for 750,000 volts with the middle-point grounded. In the testing of insulators an artificial ground is commonly used for the higher voltages. This method of testing is economical in the respect that it requires a transformer insulated for only one-half the potential necessary when test specifications require that one terminal be grounded; but it is open to doubt whether tests made in this manner are as exacting as those made with one side of the circuit grounded. Testing transformers may now be obtained suitable for intermittent testing up to 600,000 volts with one terminal grounded, and up to 750,000 volts with the middle-point grounded. One testing transformer in present service has been tested up to 720,000 volts, effective (by spark-gap measurement), with one end grounded; another has been tested momentarily up to 900,000 volts, effective (by spark gap), with the middle-point grounded. The voltage impressed on the primary is raised either by cutting out resistance as in the potentiometer method of controll or by employing a dial and a separate regulator transformer.

**200. Bell-ringing transformers.** The bell-ringing transformer, connected to a 110-volt, 60-cycle, lighting circuit, produces at its secondary

*See article in *Electric Journal* for October, 1914, by Shaw.

Digitized by Google

terminals a voltage suitable for operating door-bells, buzzers, annunciators, miniature incandescent lamps, or for any purpose for which dry or wet-cell batteries are used. The transformer has the advantage over batteries that it requires no attention after it has been installed, and there is no further expenditure, since its life is probably indefinitely long; and, furthermore, the annoyance of having bells out of order due to battery failures is done away with. The amount of energy consumed at no load is very small, being about 1 watt. Voltages of 16 or 24 volts are obtained.

**201. Transformer equipments for thawing water pipes by electricity.** These equipments consist of a transformer having high reactance, or a transformer and an external reactance combined. When in operation, the high-tension leads are connected to the main-line feeders. The secondary leads may be connected to any convenient points in the piping system, so that the frozen portion is included in the circuit. The transformers are generally air cooled and portable.

**202. Sign-lighting transformers.** The standard practice in lighting electric signs is to use 10-volt tungsten lamps of about 4 c-p., which have a watt consumption per candle-power of only a little over one-fourth that of carbon-filament lamps of the same candle-power, and to operate these lamps in multiple, using a step-down transformer by which the pressure of the 110-volt or 220-volt supply circuit is reduced to a suitable value. These transformers are designed for use on 60 cycles, at voltages of 240, 220, or 200 volts, or at 120, 110, or 100 volts, and will deliver their full rated load at either 10 or 20 volts. The ratings and efficiencies of these transformers are as follows, in Par. **203**.

**203. Table of Ratings, Efficiencies and Weights of Sign-lighting Transformers**

| Rating in watts | Efficiency | | | | Wt. lb. |
|---|---|---|---|---|---|
| | ¼ load | ½ load | ¾ load | Full load | |
| 160 | 85.3 | 90.5 | 91.5 | 91.5 | 17.0 |
| 250 | 84.1 | 90.2 | 92.0 | 92.6 | 28.0 |
| 375 | 87.1 | 91.9 | 93.1 | 93.3 | 31.0 |
| 500 | 87.8 | 92.4 | 93.5 | 93.7 | 34.0 |
| 1,000 | 91.3 | 94.4 | 95.1 | 95.0 | 70.0 |
| 2,000 | 91.5 | 95.0 | 95.9 | 96.2 | 86.5 |

**204. Transformers for operating series incandescent lamp from series arc-lamp circuits** are essentially series-type (current) transformers of suitable dimensions and windings for the service required. They are designed to transform the current from the value in the series arc-lamp circuit to a value suitable for series tungsten lamps. Besides giving good regulation, a transformer of this kind must be arranged so that in event of the secondary becoming open-circuited while the primary current is at normal value, the rise in voltage will not be excessive. These characteristics are secured by contracting the section of the core at several points, so that the iron becomes saturated at full-load primary current and thus limits the secondary voltage to a value approximately 150 per cent. of its normal full-load value.*

## TRANSFORMER TESTING

**205. Transformer testing may be conveniently classified** as follows:

(a) Shop tests made during process of manufacture for the purpose of discovering any gross defects in the winding of coils and in the insulation of the completed transformer. See Par. **206**.

(b) Specification tests to determine whether the factory has correctly followed the engineer's specifications. See Par. **207** and **208**.

(c) Measurements of losses and determination of performance and regulation. These must meet the manufacturer's guarantees. Par. **209** to **211**.

(d) Heat tests to determine running temperature. The temperature

* *General Electric Review*, June, 1911, p. 293.

Digitized by Google

rises under certain specified conditions must meet the guaranteed values, Par. **212** to **216**.

(e) Insulation tests. These comprise the overpotential test which is made for the purpose of exposing any defect or injury in the insulation between turns, between layers, and between coils; the disruptive test for determining whether the insulation between the primary and the secondary windings and between these two windings and ground is sufficiently strong. Par. **217** to **220**.

(f) Tests on instrument transformers; calibration.

**206. Shop tests.** In the case of large power transformers these tests are sometimes omitted, but in their stead each coil is very carefully inspected during the course of winding and insulating. The tests to determine any defects in winding are made by placing each coil on a core which is furnished with a removable yoke, and inducing in each turn of the coil a specified e.m.f. A test to determine whether the insulation is intact after the coils are assembled and the iron built in, is made by subjecting the insulation between the primary and the secondary windings, and between each of these windings and ground, to a test of several thousand volts. The transformer is then ready for the testing department.

**207. Tests to determine whether the transformer is correctly wound and assembled.** The first test to make is the **ratio test.** This determines whether the transformer has been wound correctly and the leads and tap brought out in the right places. The methods used in making this test will depend upon the transformer to be tested. Large power transformers are tested for ratio by having a fraction of the normal voltage impressed on a winding while the voltage between taps is measured by means of a voltmeter, and the ratio of the tap voltage to the total is thus obtained. The ratio of the primary voltage to the secondary voltage is obtained in the same manner. Small transformers for lighting and small power service may be tested by balancing against a standard of known ratio. The same method applies to shunt-type (potential) transformers for instruments.

**208. Polarity test.** In power transformers this test follows the ratio test, and is made by connecting two adjacent primary and secondary

leads together and noting whether the secondary e.m.f. is thereby added to the primary e.m.f., or subtracted from it. In the case of small transformers, the ratios of which are tested by comparison with a standard, the polarity is given at once by reference to that of the standard. Thus the apparatus for testing may be so arranged that if the polarity of the trans-

Digitized by Google

former to be tested is wrong, a red pilot lamp becomes energised. This method of determining polarity is characteristic of all balance methods applied to alternating-current work, such as, for instance, the shunt-resistance method of testing the ratio and the phase displacement of series-type (current) transformers.

**209. Measurements of losses** comprise those for core-loss, and those for copper-loss and impedance volts. The core-loss consists of both hysteresis and eddy-current losses in the iron. Since the "flux-linkages" are the time integral of the induced e.m.f., and since all commercial e.m.f. wave-forms contain the odd harmonics only, the maximum value of $B$ will be determined by the average value of $E$. And therefore the hysteresis loss will depend, not on the root-mean-square value of $E$, but on its average value. The eddy-current loss, on the other hand, will depend on the root-mean-square value of $E$. Hence the core-loss, to be measured accurately, must either be obtained on a circuit having an e.m.f. wave, whose average value and root-mean-square value have a specified ratio (the standard wave is sine-wave and the standard ratio of root-mean-square to average value is 1.11), or else compensation must be made for any deviation from this ratio by some device which indicates how much to raise or lower the voltage to obtain the correct loss. It is essential in the former case that the wave form at the terminals of the transformer, after correction has been made for wave distortion due to voltage, regulating devices, etc., shall be such that this ratio is equal to 1.11. The second method may be used with the aid of an **"iron-loss voltmeter"** (Sec. 3). Fig. 44 shows the connections used for measuring iron-loss. When the iron-loss voltmeter is used it should be connected in circuit with the root-mean-square voltmeter: both readings should be noted and correction made for the shunt loss of the wattmeter from the readings of the root-mean-square voltmeter. Strictly speaking, the loss should be taken with both voltmeters in circuit and corrections made for their losses also. The iron-loss voltmeter is provided with a scale by which its loss may be read directly.

**210. In measuring the core-loss care should be taken** that when a portion, only, of the winding of the transformer is used it is so situated that

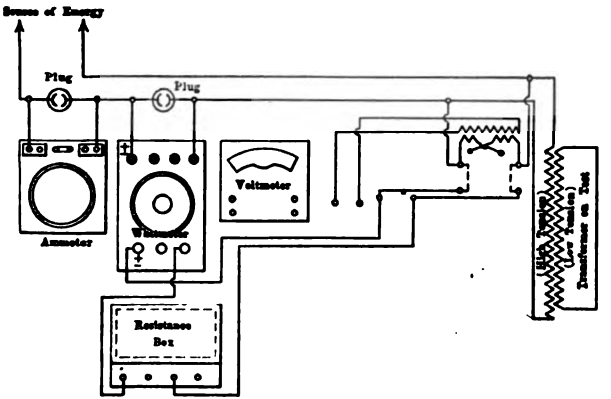

FIG. 45.—Connections for making copper-loss and impedance-drop test.

the magnetic leakage is practically the same as under normal open-circuit conditions. In general it is better to sacrifice a little in convenience and use the whole winding, than run the chance of error by using a portion of the winding. The value of impressed voltage used when the measurement is made on the secondary side should be the rated voltage plus the secondary $IR$ drop. The **equivalent sine-wave exciting current** is obtained by

Digitized by Google

the ammeter reading, and the true-watts component is obtained by dividing the observed core-loss by the value of rated secondary voltage plus the secondary $IR$ drop.

**211. Copper-loss and impedance volts.** This measurement is made by short-circuiting one winding (properly it should be the primary winding) and circulating rated full-load current in the other, observing the loss in watts and the impressed voltage. The connections for the test should be made as shown in Fig. 45. The current should be adjusted with the voltmeter and the wattmeter shunt winding disconnected. The wattmeter may then be read first, followed by the voltmeter. If the exciting current of the transformer is high, a correction, obtained from Eq. 11, Par. **24**, must be added to the copper-loss measured as above. The copper-loss so obtained will be the true copper-loss of the transformer and includes the eddy-current loss in the conductors. By dividing the copper-loss by the rated output, the effective $IR$ drop, expressed as a fraction of the rated voltage, will be obtained. Divide the observed voltage by the rated voltage, and the effective impedance-drop, expressed as a fraction of the rated voltage, will be obtained: the effective reactance drop, expressed as a fraction of the rated voltage, may then be obtained by taking the square root of the difference of the squares of these two quantities. Efficiencies and regulation may then be computed from these results by the usual formulas, which are given under "General Theory," Par. **24** to Par. **26**.

**212. Tests for efficiency of cooling** include the measurement of temperature rise above the cooling medium at various loads. Resistance measurements are also included, because they are necessary to determine the rise in temperature of the copper.

**213. Resistance measurements** may be made with a Wheatstone or a Kelvin bridge of the proper range. The conditions for measuring the cold resistance should be carefully prepared, so that the apparatus whose resistance is under determination will be at the temperature of the surrounding air. If the temperature of the room fluctuates, it is recommended that an idle unit be employed, of the same design as those on test. The resistance of the winding of the idle transformer may then be used as a basis from which to measure the temperature, by increase of resistance of the loaded transformer.

**214. Methods of loading.** There are various methods of artificially loading transformers. The best method, where two or more transformers

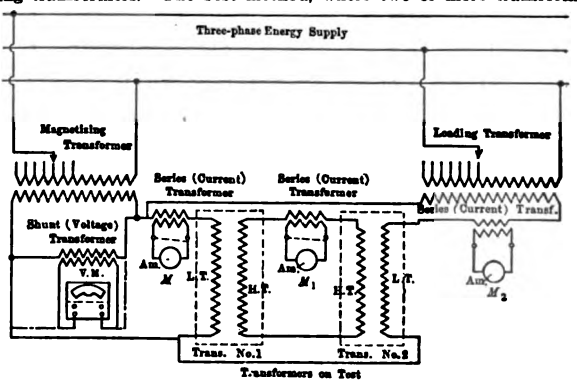

FIG. 46.—Method of artificially loading a transformer (opposition method).

are obtainable, is the **opposition method.** The simplest arrangement of this method is illustrated in Fig. 46. Two transformers are connected as if for multiple operation; then one of the connections of one set of windings is

Digitized by Google

opened and full-load current is circulated in the circuit from an external source of energy. Either pair of windings is then excited from a suitable source at proper voltage and frequency. It is preferable that the time-phase relations of the exciting e.m.f., and the current-circulating e.m.f., should be capable of variation, so that the conditions of load may be varied to suit different requirements. Another method of loading is the "**Alternate open-circuit and short-circuit method.**" A full discussion of this method may be found in the proceedings of the A. I. E. E., Feb., 1913, in papers by Fortescue, McConahey and Madden.

**215. Measurements of temperature.** After steady conditions have been reached, as indicated by thermometers placed at various points in the windings, preparations should be made for taking the **hot resistance.** To insure prompt measurement, the instruments should be set before-hand for the expected values, so that a quick adjustment may be made.

**216. In making the heat test both wattmeters and ammeters may be used.** The wattmeters may be arranged to read the total core-loss, the total copper-loss, and the power input or output. The power-factor of the load may be obtained and adjusted.

**217. Insulation tests** include **overpotential tests** for the purpose of determining whether the insulation between turns and coils is intact; and **disruptive tests** to determine the condition of insulation between primary and secondary windings and between these windings and ground. Sometimes, also, the **insulation resistance** between primary and secondary windings is measured.

**218. Overpotential test.** For large transformers an overpotential of double the rated low-tension voltage is usually applied for 5 min. to the low-tension terminals. It is desirable when making this test on high-voltage transformers to disconnect the high-voltage winding so as to reduce the voltage. In small transformers an overpotential of five times rated voltage at 500 cycles may be used. The overpotential test should be made while the transformer is hot.

**219. Disruptive test.** In making this test on power transformers the low-tension winding is connected to the iron and to ground, and the primary winding is connected to one end of a testing transformer, the other end of which is grounded. A sphere spark-gap should always be used, with tests above 50,000 volts, for measuring the voltage, as a rise in voltage is likely to occur in the testing transformer. The usual test is from two to two and one-half times line voltage. The Standards Committee of the A. I. E. E. give definite recommendations in regard to the tests to employ, and it is customary to follow them. Small transformers for operation on 2,200-volt circuits should receive a test of 10,000 volts for 1 min.

**220. Tests on instrument transformers.** Instrument transformers, if they are to be used for precise measurements, must have a calibration curve made for the conditions of load under which they will be operated. These calibration curves give the ratio and the phase displacement for different current-values. For methods of obtaining calibration curves on instrument transformers, see Sec. 3.

**221. Instruments used for testing should be carefully chosen.** The use of series (current) transformers and shunt (potential) transformers should be avoided unless they have been calibrated for the particular instruments to be used. In testing with high-voltage transformers at pressures above 50,000 volts, a sphere spark-gap should always be used, both for measuring the maximum of the applied voltage and also for the protection of both the testing transformer and the apparatus to be tested. The sphere gap can be relied on as an accurate method of measuring the maximum value of the applied voltage.*

## INSTALLATION, CARE AND OPERATION

**222. General.** A transformer is usually very rugged and is capable of withstanding a great deal of abuse; nevertheless, it will be found to respond to good treatment by exhibiting longer life and higher operating efficiency.

Digitized by Google

**223. Shipping and unpacking.** Before leaving the factory, transformers are carefully packed. They are now generally shipped in their tanks with oil, and are ready for operation as soon as they arrive; but it is always a wise precaution, particularly with high-voltage transformers, to draw off from the bottom of the tank some of the oil and give it the usual disruptive test. If the dielectric strength is not high enough the oil should be dehydrated (Par. 232). This may be done without removing the transformer from the tank, by drawing the oil from the bottom of the tank through the dehydrating outfit and returning it at the top; this should be continued until repeated tests show the oil to be in good condition. If the transformer has been shipped in a packing case, and is one of a high-voltage type, it should be dried out before installation, unless it is hermetically sealed in an air-tight metal casing. The safest and best method that can be used to dry out a transformer is to force dry air at a temperature of 90° C. through the windings. Grid resistances may be used for heating the air, and it may be forced through the windings by a blower.

**224. Precautions in making connections.** When installed ready for operation the transformers should be carefully inspected to see that they are all connected properly, both internally and externally; that all switching apparatus is in good working order; and if new banks are to run in multiple with previously installed banks, it should be noted that they are connected at the proper operating taps, and so as to have the same polarity as the older banks. If the new transformers are of the same manufacture as the old, the polarity will be the same as that of the old, if the banks are similarly connected. If they are of different manufacture from the old, the polarity when similarly connected may be such as to make parallel operation impossible. It is therefore a wise precaution to check up the relative polarity of the old and the new banks before connecting together. This may be done by connecting the new bank on the high-tension side and connecting one of the low-tension terminals to the common bus bar; then, with a voltmeter, and if necessary with the aid of a shunt (potential) transformer, measure the voltage between the other two terminals and the respective busses with which they are to connect (a bank of lamps may be used instead of a voltmeter, with 110- or 220-volt connections) and observe the following **rules**:

(a) **If the polarities are alike** the voltmeter will read zero, in each case.

(b) **If the polarities are reversed** the voltmeter will read, in each case, double the secondary voltage. The remedy is to reverse the connections of the low-tension leads of each transformer in the new bank. (In three-phase transformers it may be found more convenient to reverse the connections of the high-tension coils.)

(c) **In three-phase transformers** the following cases may be met, in addition to the above. Having two similarly located low-tension terminals, of the old and new banks, connected together, the high-tension terminals of each bank being similarly connected to the same source of e.m.f., measure the voltage between corresponding free low-tension terminals.

(c-1) **If one voltmeter reads the secondary voltage correctly and the other reads double this value,** the external polarity of the two transformers is the same, but the terminals are in different order. The remedy is to interchange the internal low-tension connections to the terminals of the new transformers, so that the lead connected to the terminal for which the voltmeter reads double voltage will take the place of the lead connected to the terminal tied to the corresponding terminal of the old transformer. Equivalent external transposition may be made instead.

(c-2) **If one voltmeter reads zero and the other reads 1.73 times the secondary voltage,** then we have a case of reversed external polarity and transposition of terminals, combined. The remedy in the case of a delta connection is to disconnect the ends of the two coils from the terminal showing high voltage and connect the other ends of these two coils to this terminal; the ends previously removed should then be connected to the two remaining terminals, so that a coil that was originally connected to any one of these two terminals will now be connected to the other one. An equivalent change of connections must be made in the case of a star connection.

**225. Multiple connections.** Transformers having like primary and secondary connections may be run in multiple with one another, but transformers having unlike primary and secondary connections cannot be made to run in multiple with the former except by the use of auxiliary devices,

Digitized by Google

such as auto-transformers. It is of great importance, therefore, when buying transformers for multiple operation with previously installed banks, that the connections of the latter are given.

**226. Where independent energy sources supply each bank of transformers, relative polarity is of no consequence,** nor is it of any importance whether the primaries and the secondaries are both delta-connected, or one delta-connected and the other star-connected.

**227. Causes of insulation failures.** First, inadequate insulation strength at the point of failure. Second, imperfect mechanical supporting and bracing of coils, so that when subjected to the short-circuits that occur under operation, the coils are deflected or buckled, thereby tearing or weakening the insulation, which otherwise would be quite adequate. Third, poor design in the matter of cooling, such that while showing a normal temperature by thermometer or by rise of resistance, the windings have portions that are blanketed or far removed from the cooling medium; in other words, have "hot spots." Such a condition will, in the course of time, cause a weakening of the mechanical strength of the fibrous materials of which the insulation is composed, so that with the least jar the insulation is broken and an internal short-circuit results. Fourth, imperfect operation of apparatus on the line, such as circuit-breakers, electrolytic lightning arresters, etc. Fifth, improper operating conditions, such as overloading, or multiple operation without a proper division of load. Sixth, lack of care in regard to conditions of oil, dirt, moisture, etc. Seventh, direct stroke of lightning. Assuming that the transformer has been carefully designed in every feature, only the last four causes need receive consideration.

**228. Line disturbances.** The operation of circuit-breakers, charging of electrolytic arresters, breaking down of line insulators, and short-circuits on the line, all create disturbances which produce more or less stress on the transformer insulation; but transformers are insulated to withstand the stresses due to the above causes as they arise under normal working conditions. When, however, circuit-breakers fail to operate properly, these stresses may be unusually severe. It is therefore important to see that all protective devices are in perfect working order. With certain connections, such as the Scott connection and the "*T*"-connection, the charging of electrolytic lightning arresters may cause unusually severe stresses. The behavior of the transformers under such conditions should be carefully observed and if any unusual conditions are present they should be looked into.

**229. Improper operating conditions** are very often the source of transformer failures; particularly due to the fact that lack of care in other matters goes hand in hand with carelessness in operation. Conditions sometimes arise under which it is imperative that a transformer be overloaded for a considerable length of time. After such an overload, the transformer at the first opportunity should be examined to see that the ducts have not become clogged by any deposits from the oil. Transformers should not be operated for any great length of time on a system, one line of which has become grounded; the factor of safety in such operation is only one-half of that under normal operating conditions.

**230. Grounded secondaries.** Troubles may be caused when supplying energy for lighting from high-voltage polyphase circuits, due to the relative electrostatic capacity of the high-tension and low-tension circuits, to each other and to earth. This condition may cause high insulation stresses in the low-tension circuit, and may shock anyone touching the low-tension circuit sufficiently to cause death. The only remedy for this condition is to ground the secondary circuit, preferably at the neutral point. (See National Electrical Code, and also Sec. 12 and 13.)

**231. Care of transformer oil.** Lack of attention to such details as the periodic inspection of transformers, and testing of the oil, is responsible for most transformer failures. The oil in a high-voltage transformer should be tested once a month and if its strength is below par it should be dehydrated (Par. 232). It must be remembered that the oil furnishes one-half the insulation strength of the transformer.

**232. The best method for dehydrating oil** is by the use of the filter-press type of dehydrator. In this type the oil is pumped through several

Digitized by Google

thicknesses of a blotting paper. When using this apparatus it should be seen that the paper is carefully dried, and it is better to soak it, first of all, in clean oil that is perfectly dry. Fig. 47 shows this form of oil dehydrator. When the oil is in very bad condition, the paper should be changed from time to time, as often as found necessary. Oil in first-class condition should break down at not less than 40,000 volts, with a gap of 0.15 in. between ½-in. spheres.

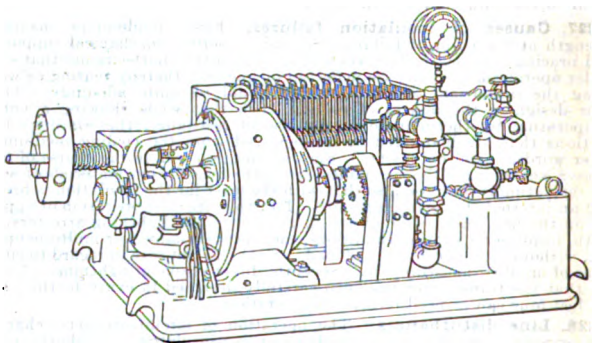

FIG. 47.—Filter press type of oil dehydrator.

**233. Regulation of quantity of cooling medium.** When water-cooled transformers are subjected to heavy overloads the water rate should be increased correspondingly. Any oil-immersed transformer will withstand a heavy load, for a short period very much better than an air-cooled transformer. Allowance should therefore be made in operation for the cooling characteristics of the transformers, and where artificial means are used for cooling, the cooling may be improved under abnormal load conditions by using more of the cooling medium.

**234. The oil-piping layout of transformers** when installed should be arranged so that the oil in any unit may be filtered without disturbing the others; there are several obvious methods of accomplishing this. Whatever scheme be used, care should be taken that all the air is removed from the oil in the transformer tanks; this may be done by creating a vacuum under the cover during the process of pumping.*

**235. A transformer when burned out or defective** should immediately be replaced by a spare unit if one is available. A careful examination should then be made of the windings; if nothing is disclosed, the transformer should be returned to its tank and measurements made of its open-circuit losses. If there are any short-circuited turns or layers, the open-circuit losses will be abnormally high. The location of the trouble can generally be traced by the blackening due to smoke, and by feeling the coils, after first removing the exciting voltage, for the point of highest temperature. If either of these methods fail, measurement may be taken of the resistance of primary and secondary windings; a short-circuit will be indicated by a lower resistance than normal. In many cases, however, a short-circuit which cripples the transformer may involve only a few turns in a large total number, so that the continuous-current resistance measurement may not be sensitive enough to detect it.

**236. Formation of scale in cooling coils.** A water-cooled transformer may progressively increase in temperature and appear to be defective, due to no apparent cause. In such a case the cause of the trouble can generally be traced to the water supply, which will be found to contain foreign matter in solution, such as lime and carbonates; these impurities, when the water becomes heated in passing through the tubes, are precipitated in the form of

* *Electrical World*, Feb., 1913, p. 360.

Digitized by Google

scale, which, in addition to being a bad conductor of heat, chokes the flow of water.

**237. Criterion for replacing inefficient transformers with units of higher efficiency.** A transformer should be replaced by another of higher efficiency when the difference in cost of operating the two is greater than the interest on the additional capital that would be invested in the change. It is in most cases exceedingly difficult to calculate the cost of operating a transformer, and for that reason it is well to be conservative in making such changes. Lower operating cost may be disclosed in either of the following ways: Decreased total plant depreciation; decreased coal-bill; decreased total investment per kv-a. of peak load; and increase in energy sold per annum per dollar of investment. In the case of transformers for residence lighting, it is well to bear in mind that very few lighting and power plants have as much day load as they can carry economically, but the majority of them have all the peak load they can carry. The losses of transformers during the slack-load period are therefore not of much importance, whereas at the time of the peak load, when every kw-hr. of available energy means revenue, the cost of each kw-hr. of iron and copper losses in transformers is very high.

## REGULATORS

### POTENTIAL REGULATORS

**238. General principles.** The principle of operation of all potential regulators consists in changing the mutual inductance between the primary and the secondary windings of a transformer or auto-transformer, either by mechanical means or by changing the ratio of the two windings.

**239. The variable-ratio type of regulator** is simply a transformer provided with means for changing the secondary e.m.f., either by cutting out portions of the winding, or by opposing or adding the e.m.f. of auxiliary windings of the transformer provided for this purpose. These auxiliary windings are provided with taps, so that their voltage may be increased or decreased, step by step. The secondary winding proper has only a few taps, the voltages of which are "bucked" or "boosted" by the auxiliary coils, according to the position of the regulator drum. In this way a large range of regulation may be provided with a comparatively simple equipment. Auto-transformers are sometimes used instead of the auxiliary windings. They have some advantage over the auxiliary winding scheme because finer steps are obtainable thereby.

**240. The single-phase induction regulator** depends upon mechanical means to produce this change in mutual inductance (Par. **238**). It consists usually of a stationary primary wound in a slotted field, and a secondary wound on a drum-shaped core which is rotatable with respect to the primary. The secondary e.m.f. is always practically in time phase with, or in time phase opposition to, the e.m.f. in the primary circuit.

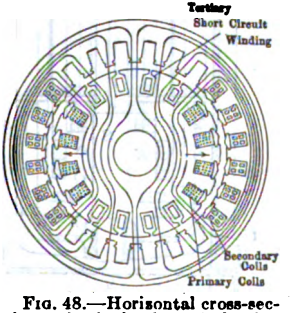

FIG. 48.—Horizontal cross-section of single-phase induction regulator.

**241. The simplest conception of an induction regulator** is a transformer with variable mutual inductance, and it may therefore be represented by the circuit shown in Fig. 4 (Par. **19**). When $M$ becomes zero, the secondary inductance is $L_2$, which is very high: to overcome this defect another independent winding, short-circuited on itself, is wound on the primary core in electrical space-quadrature with the primary winding. A current is induced in this tertiary winding, depending upon the electrical space-phase difference between it and the secondary winding, which reduces the self-inductance of the latter.

**242. Definitions of currents in a potential regulator.** The secondary current is the line current, and the primary load current is that current

Digitized by Google

which counterbalances the magnetising or demagnetising effect of the secondary current.

**243. The variation of secondary e.m.f.** with change in angular position, for a certain type of single-phase potential regulator is shown in Fig. 49. A vertical cross-section is shown in Fig. 49.

**244. The polyphase regulator** in every essential detail, is a polyphase induction motor, the polyphase coil-wound rotor of which can be locked in any position desired. The primary windings are connected across the supply lines, precisely like the primary windings of a polyphase induction motor; however, the secondary phase-windings of the induction regulator, instead of being closed upon themselves, as is true of the secondary windings of an induction motor, are separately insulated and separately connected in series with the delivery circuits from the regulator. When polyphase e.m.fs. are impressed upon the primary windings, the e.m.f. generated in each secondary coil is of the same frequency as the primary e.m.f. and its value is entirely independent of the mechanical position of the movable member; the time-phase position of their e.m.fs., however, varies directly with the electrical space position of the movable member. (Compare with the single-phase induction regulator; see Par. **240**.) The resultant delivered e.m.f. is the

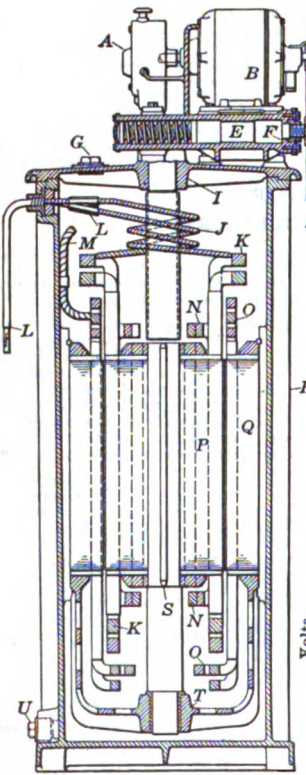

FIG. 49.—Vertical cross-section of single-phase induction regulator.

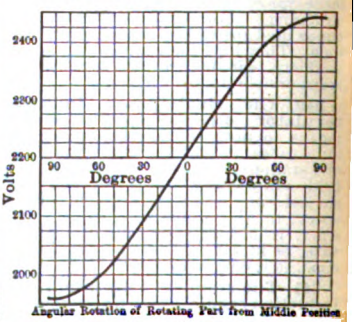

FIG. 50.—Secondary voltage of single-phase potential regulator of varying positions of rotating mauler.

vector sum of (or difference between) the primary and the secondary e.m.fs.; it is not constant in value but varies largely with the position of the movable member.

**245. Currents and m.m.fs. in polyphase regulators.** The current in the delivery circuit (which is the same as that in the secondary coil) depends directly upon the delivered resultant e.m.f. and the impedance of the delivery circuit. In the polyphase induction regulator there is no special "tertiary" circuit, but each primary phase-winding acts in part as

Digitized by Google

the tertiary circuit for the remaining primary phase-windings and the several secondary phase-windings. Thus the m.m.f. of the current in any secondary phase-winding, in any position whatsoever, is fully counterbalanced (except for magnetic leakage) by the m.m.f. of the current, or currents, of one or more primary phase-windings, and the reactance of the secondary is reduced to that due to the magnetic leakage between the stationary and the movable members.

**246. Feeder voltage regulators,** of either the step-by-step type or the induction type, may be operated by a motor, which in turn may be controlled by a voltage relay arranged to start the motor in positive or negative direction according as the voltage is low or high. A polyphase induction motor is usually employed, except when polyphase energy is not available; in this case a single-phase series motor may be used. The motor is stopped, when the relay opens, by means of a magnetically operated brake. The relay may be used in connection with a line-drop compensator (Par. **194**), so that the voltage at the centre of distribution may be automatically kept constant at any desired value.

**247. Pole-type feeder voltage regulators.** Small feeder voltage regulators arranged for mounting on poles have been brought out by one firm of manufacturers. In many lighting systems, consumers may be supplied from one common feeder in such a way that there is no definite centre of distribution; thus consumers on short branch feeders may receive perfectly satisfactory service, whereas others served from long branches may receive poor service due to the larger drop in such branches. It is claimed that a saving may be effected by installing one of these pole-type, automatic, feeder voltage regulators instead of increasing the cross-section of the branch feeders. The regulator proper consists of a shuttle-shaped rotor on which the primary is wound in one coil; the rotor also carries the tertiary short-circuited winding. The secondary is a single, form-wound, undistributed winding, fitting in two slots in the stationary core.

The regulator is operated by a single-phase induction motor provided with a starting clutch, and is controlled by a voltage relay which may be adjusted for any voltage from 10 per cent. above to 10 per cent. below normal. The relay may also be used in connection with a line-drop compensator, which has to be installed outside of the regulator. The regulator and mechanism are suspended in a cast-iron tank, and the lower part, containing the regulator core and coils, is filled with oil.

**248. Vector diagram of e.m.fs. in polyphase regulator.** Referring to Fig. 51, let $OA$ represent the e.m.f. of a certain primary phase both in value and time-phase position. Let $OE$ (or $OD$) represent the e.m.f. of the corresponding secondary phase-winding in the maximum positive (or maximum negative) boost position. Let $OE$ (or $OD$) simultaneously represent the mechanical position (in electrical space degrees) of the moving member when the secondary e.m.f. is in time-phase with (or time-phase opposition to) the primary e.m.f. In any mechanical position of the moving member, such as $OD$, the secondary e.m.f. has a value equal to $OE$ (or $OD$) and its timephase position is correctly represented by the line $OL$ provided that the "revolving field" which is the resultant of the fluxes set up by the separate primary phases is constant in magnitude. In Fig. 51 the primary e.m.f. is $OA$ and the secondary e.m.f. is $OB$, the resultant e.m.f. is $AB$.

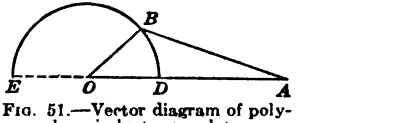

FIG. 51.—Vector diagram of polyphase inductor regulator.

## CURRENT REGULATORS

**249. General principles.** This apparatus generally consists of an adjustable reactance, which may comprise a winding on an open magnetic circuit. The coil is counterbalanced, so that with a change in the load reactance the coil will so adjust itself with respect to the core that there will be no change in the value of the current. If a large reactance be placed in series with a lesser non-inductive resistance, and a constant e.m.f. be impressed, the current will vary but slightly with this resistance "all in" or "all out" of circuit. The actual ratio of the currents with resistance "all in"

Digitized by Google

and "all out" will be equal to the value of $\sqrt{1-(\text{power-factor})^2}$, the power-factor being the value with resistance all in. It is evident that if the operating power-factor be made low enough, a series system of incandescent lamps may be operated at constant current, from a constant-potential source, with very little variation in the series reactance.

**250. Limitations.** The constant-current regulator is manufactured as a standard apparatus by a few companies, but it cannot advantageously take the place of the constant-current transformer, since it requires an additional transformer for insulation purposes (see National Electrical Code); it may, however, be used to advantage instead of the constant-current transformer where it is not required that the receiver circuit be insulated from the supply circuit.

**251. Types and characteristics.** The usual type manufactured is air-cooled and of the form described in Par. **249**. An automatic constant-current regulator may also be made by connecting in opposition two coils which surround a closed magnetic circuit, using their leakage reactance for the regulating reactance. The two coils are pivoted so as to approach each other at the middle of the core. In action they will repel each other with a force nearly proportional to the current, for any position; with proper counterweight, therefore, the current will automatically be kept constant.

**252. A motor-controlled potential regulator may be used as a constant-current regulator** by controlling it from a constant-current relay; it is usually, however, too sluggish in operation to give perfect satisfaction.

## REACTORS

**253. General types. Reactors, choke coils, or reactances for power purposes may be divided into two classes,** viz., those in which iron is used and those in which no magnetic material whatever is used. The first type consists of a coil encircling a circuit of iron which is usually broken by an air-gap or a series of air-gaps. The second type is simply a carefully constructed, circular coil of rectangular cross-section, of suitable proportions for cooling, and well supported mechanically.

**254. Iron core reactances.** The fundamental equations and general design are the same as for constant-potential transformers. The air-gap should be subdivided so as to avoid concentrated leakage, which causes eddy currents in the conductors (which are difficult to eliminate) and also makes it difficult to calculate the reactance accurately. The relative amount of copper and iron will be determined largely by the condition for minimum cost, but where the conductors are very large, it is advisable to increase the area of the core and reduce the number of turns in order to keep down the eddy-current losses in the conductors. In winding with multiple conductors every care should be taken to see that the reactance of each conductor and its resistance is the same; this may be accomplished by properly distributing the "start" and "finish" leads of the conductors.

If the length of the air-gap is $l$, the required inductance $L$, the current $I$, the number of turns $n$, the effective area of the air gaps must be obtained and it will depend on their number and distribution. The value of $\mathfrak{G}$ may then be calculated from this area by Eq. 4, Par. **5**.

Thus the value of $l$ will be

$$l = \frac{4.51nI}{\mathfrak{G}} \qquad \text{(in.)} \qquad (71)$$

where $\mathfrak{G}$ is the induction in lines per sq. in.

**255. The current densities and the flux densities** will be about the same as for transformers. The methods of insulating the coils are very similar and need no special treatment here, as they are covered under the heading of "Insulation," Par. **41** to Par. **47**.

**256. Cooling** may be effected by any of the various methods applied to transformers. The problem is the same in every particular and is treated under that heading, Par. **61** to Par. **70**.

**257. Applications. Iron reactors for power purposes** are mostly used in connection with compound-wound rotary converters to obtain compounding or overcompounding of the voltage at the continuous-current terminals. Iron reactors are also used to shunt the series coils of compound-

Digitized by Google

wound continuous-current machines, in which case they are known as **inductive shunts.** They may be used for innumerable purposes, such as compensating for the leading current in cable testing; for compensating long telephone circuits (**Pupin coils**); shunting series incandescent lamps (**economy coils**) to prevent an open circuit as the result of a lamp failure, etc.

**258. Air reactors** for precise measurements are made of a single layer of fine enameled wire, carefully wound on a marble cylinder that has been made as nearly perfect as possible; such reactors are used as absolute standards. Power-limiting reactors are described in Par. **259** and **260.** The **reactance circuit-breaker** makes use of an air reactance to limit the current at the initial break so that a circuit may be opened in two stages; the first stage being the introduction of the reactance, and the second stage being the complete opening of the circuit. Air reactors have also been put into service for supplying lagging current to compensate for the leading current due to the distributed capacity of transmission lines; and are inserted in series with transmission lines (**choke coils**), for protection against lighting disturbance. Their office in the last instance is to choke back any line surge that may arise and prevent it from injuring the station apparatus.

**259. Power-limiting reactors** are now usually made with no magnetic material, although the first reactors made for this purpose and installed in the Cos Cob station of the New York, New Haven & Hartford Railroad Co. were of the iron-core type with distributed windings.

**260. Methods of winding power-limiting reactors.** The methods of winding adopted by the various manufacturers do not differ materially. Thus one firm winds with long cylindrical layers, using wooden cleats as separators; another firm uses flat discoidal-shaped layers or sections, each conductor of which fits into a groove in porcelain cleats; the cleats when clamped together insulate and separate the individual layers. A third firm uses methods similar to the second, but for cleats employs moulded heat-resisting material as a substitute for porcelain. See Fig. 52.

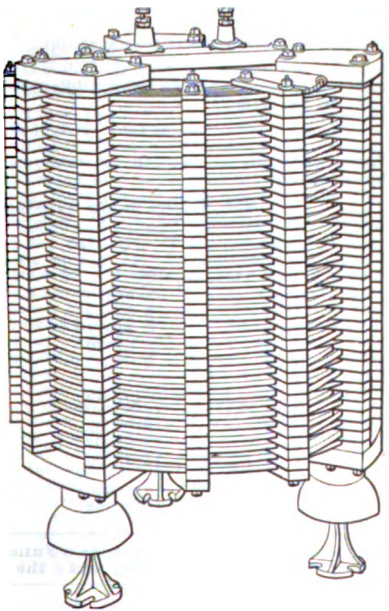

FIG. 52.—Power-limiting reactor.

**261. Cooling of power-limiting reactors** is effected by natural circulation or air blast. The arrangements of winding are particularly well adapted for cooling by the last method.

**262. Mechanical stresses in the windings,** while severe, are not of such a nature as to produce any trouble. Thus the radial stresses tend to elongate the conductors, while at the same time they produce a compressive action on the coil section. The axial stresses are compressive and tend to crush the conductors into less space. These forces are difficult to calculate with any degree of accuracy, but experience has shown that with the methods of winding which have been described, and with reasonable care in

Digitized by Google

installing, reactors will be amply strong enough to withstand any stress that may arise in service.

**263. Formulas for self-inductance.** The inductances of coils at commercial frequencies may be calculated with a high degree of accuracy, provided the proper formula is used. The following formula, which is Lorens's cylindrical current-sheet formula with a correction for thickness of coil, will be found accurate. Refer to Fig. 53 for dimensions which are assumed to be inches.

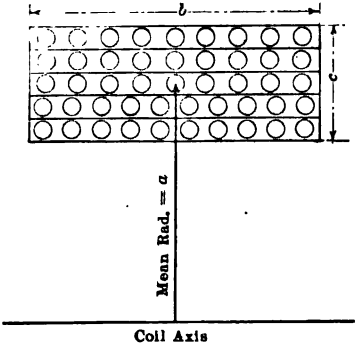

FIG. 53.—Cross-section of reactance coil.

**264. Rosa's formula.** This is accurate for any shape of coil. For practical work the correction for the form of the conductor is negligible and may be omitted; the formula then becomes

$$L = L_s - \Delta_1 L \qquad (72)$$

To obtain the value of $L_s$ the formula below may be used (Eq. 73):

$$L_s = an^2 Q \times \frac{2.54}{10^9} \text{ (henrys)} \qquad (73)$$

Where $Q$ is a function of $2a/b$, the values of which for different values of this ratio are given in the table below, in Par. **265**. The correction term $\Delta_1 L$ is given by the formula

$$\Delta_1 L = 4\pi a \left(\frac{b}{c}\right)(A_s + B_s) \times \frac{2.54}{10^9} \text{ (henrys)} \qquad (74)$$

Where $A_s$ and $B_s$ are given in the tables below (Par. **266** and Par. **267**) as functions of $c/a$.

**265. Values of the Constant $Q$ in Eq. 73**

**268. The formula for a coil of square cross-section,** as obtained from Weinstein's formula, is

$$L = 4\pi an^2\left[\left(1+\frac{c^2}{24a^2}\right)\log_e\frac{8a}{c}+0.03657\frac{c^2}{a^2}-1.195\right]\times\frac{2.54}{10^9} \text{ (henrys)} \quad (75)$$

It may be shown that with a coil of square cross-section, in order to obtain maximum inductance with a given weight of copper, the ratio $a/c$ must be approximately 1.47.

## RECTIFIERS

### MERCURY-VAPOR RECTIFIERS

**269. General.** The mercury-vapor rectifier is exceedingly simple in structure. The single-phase type consists of a chamber from which the air and all foreign gases have been exhausted, and in which there is a mercury pool connected to a terminal which passes through the chamber; projecting into the upper part of chamber are two terminals of iron or graphite which are commonly called the **anodes** (but which in actual service are alternately anode and cathode), the mercury pool being termed the **cathode.** The general arrangement is shown in Fig. 54. In addition to the above, there may be a **supplementary anode** which may be a separate rod or, in **glass-bulb** rectifiers, a portion of the mercury pool separated from the remainder by a slight space. This supplementary anode is used for starting or exciting the rectifier; when used for starting only, a tilting mechanism is provided which enables the two edges of the mercury pool to be brought together, closing an auxiliary circuit, and thus causing a spark or arc to form where the edges recede. Once the rectifier starts, it will continue to operate if the proper amount of inductance is included in the circuit. Where the supplementary anode is used for continuous excitation, it is connected to a source of direct current. Where the mercury pool is divided into three small pools, the two outer pools may be used as anodes with the centre pool as cathode, and a continuous arc may be supplied for sustaining purposes by means of a small auxiliary transforming device or auto-transformer.

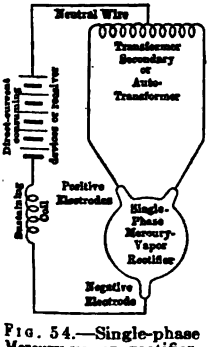

FIG. 54.—Single-phase Mercury-vapor rectifier.

**270. Characteristics.** From the viewpoint of the electrical engineer the mercury-vapor rectifier may be considered as an electrical valve, which permits current to flow only from a positive terminal to the pool of mercury. Thus, as long as the terminal has a certain definite potential above that of the mercury pool, current will pass, but the moment that this potential becomes lower than this critical value, the current commences to decrease.

Digitized by Google

**271. The theory of operation.** An ionising agent is required to start the electron stream issuing from the cathode. The liberated electrons proceed at high velocity toward the anode ionising molecules of gas on their course thereby producing positively charged bodies and increasing the stream of electrons moving toward the anode. The positive charges are drawn toward the cathode where they become neutralised again or negatively charged; in so doing they further increase the ionization at the cathode, and produce in its neighborhood a high intensity or potential gradient which assists in accelerating the electrons emitted at the surface of the cathode. The neutral or negatively charged molecule is forced back toward the anode, but becomes ionised again by the stream of electrons issuing from the cathode. The negatively charged molecules apparently rarely move far enough away from the cathode, before becoming ionised by collision, and positively charged, so as to come under the influence of the electric field of the inactive electrode. There is, therefore, no leakage or an extremely small one between the active and inactive anode.

**272. In the actual design of rectifiers** it appears that rectifying power is dependent upon the extent of the dark space surrounding the inactive terminal, which is known as **Crooke's dark space.** This space increases in volume as the vapor pressure decreases. The rectifying power is therefore enhanced by keeping the vapor pressure low, which means operating at low temperature. Another method by which the rectifying power may be increased, is by enclosing the terminals in narrow chambers far removed from the mercury pool; this produces a rectifier much more sensitive to temperature variation than when the terminals are in a common chamber.

**273. Auxiliary apparatus.** In order to obtain unidirectional current the mercury-vapor rectifier must be provided with a **transformer,** or autotransformer, connected to the anodes so that they will be alternately positive and negative with respect to the mercury pool. The transformer (or autotransformer) must be provided with a middle tap, between the two terminals connected to the anodes; this tap and the cathode of the rectifier chamber form the two terminals of the direct-current circuit. In order to obtain a current whose instantaneous values will fluctuate between narrower limits, some means must be provided to overlap the activities of the two terminals of the rectifier, so that one will become active before the other ceases its activity. This can be accomplished by introducing inductance in the direct-current circuit, or what amounts to the same thing a high magnetic leakage between the two halves of the transformer secondary winding connected to the rectifier. Thus a magnetic field is set up by the current in the anode, which, when the current is decreasing, sets up an electromotive force which tends to hold the anode potential up to the proper value, while the rate of decrease of the current is very much slower than when the inductance is absent; and thus the current is permitted time to build up in the previously inactive anode, before the current has ceased in the other.

**274. Formulas for calculation of transformation ratio, induction, etc.** The exact calculation of wave form, ratio of direct to alternating current, etc., is a somewhat complex problem involving transient phenomena. For practical work a sufficiently close approximation to exact theory is obtained by considering the ripple in the direct-current wave to be a simple double-frequency harmonic. In the formulas that follow it is assumed that the unidirectional current is represented by a constant average value $I_a$ on which is superimposed a double-frequency simple harmonic current-wave of maximum value $I_b$: the effective value of the current is $I_e = \sqrt{I_a^2 + I_b^2}$. Let $L_a$ be the effective inductance and let $R_a$ be the effective re-

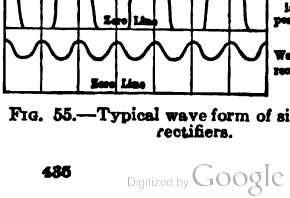

FIG. 55.—Typical wave form of single-phase rectifiers.

Digitized by Google

sistance of the two halves of the secondary winding when connected in multiple, under the condition of short-circuited primary, and let $L_b$ and $R_b$ be the effective inductance and resistance, respectively, of the two secondary windings when connected in multiple opposition; let $L_e$ and $R_e$ be the inductance and resistance, respectively, of the load; let $V$ be the back-e.m.f. in the direct-current circuit, including the cathode drop of the rectifier; and let $n_2$ be the number of turns in one-half the secondary winding.

For a given value of $I_b$ we must have a value of sustaining inductance ($L_b+L_e$) not less than

$$2\omega(L_b+L_e)=\sqrt{(R_eI_e+V)^2-(R_eI_b)^2} \tag{76}$$

The maximum value of the periodic portion of the induction in the core is given approximately by

$$\mathfrak{B}=\frac{10^8}{2\omega n_2A_1}[(\pi-\alpha)\{(R_e+R_b)I_e+V\}+\sqrt{(R_e+2R_b)^2+4\omega^2(L_e+2L_b)^2}\,I_b\sin\alpha] \tag{77}$$

where

$$\cos\alpha=\frac{(R_e+R_b)I_e+V}{\sqrt{(R_e+2R_b)^2+4\omega^2(L_e+2L_b)^2}I_b} \tag{78}$$

To this must be added the constant portion

$$\mathfrak{B}'=10^8\frac{L_bI_e}{2n_2A_1} \tag{79}$$

A set of characteristic wave forms is given in Fig. 55.

**275. The three-phase rectifier**, shown in Fig. 56, is unlike the single-phase rectifier in the respect that it requires no inductance to sustain the direct-current wave. This will be better understood by referring to Fig. 57, where $a$, $b$, $c$, are the consecutive positive voltage waves of a three-phase system. The secondary current will flow first from the anode connected to phase $a$, to the cathode, and thence through the direct-current circuit back to the neutral point of the three-phase system. This will continue until the point $h$ in the wave $a$ is reached; the current will then be transferred to the anode connected to the phase $b$; the current will continue to flow from this wave until the point $k$ is reached, when it will again be transferred, to the wave $c$; it will continue to flow from $c$ until the point $e$ is reached, when it will once more be transferred to the wave $a$, completing the cycle. The dotted line represents the cathode potential with reference to that of the neutral point of the three-phase system; the latter is the positive terminal of the direct-current system supplied by the rectifier, its potential being represented in Fig. 57 by the line ($ox$).

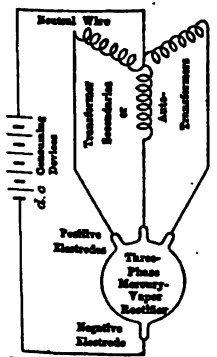

FIG. 56.—Three-phase mercury-vapor rectifier.

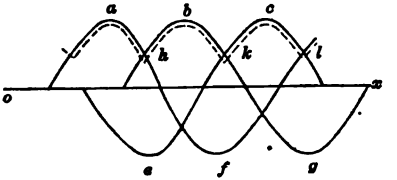

FIG. 57.

Digitized by Google

**276. A unidirectional current cannot be delivered by the secondary of a transformer** except through the medium of the magnetic circuit, which stores the energy during the inactive cycle and delivers it in the form of unidirectional current. The regulation and the power-factor in such cases are necessarily poor. In order to obtain satisfactory operation, two three-phase rectifiers are required which will operate from the secondaries of the three-phase transformer; or three single-phase transformers may be connected to give diametrical six-phase currents, the middle points of the secondaries being connected together. The rectifiers are connected so that there is one anode of each to a single secondary winding. The cathodes are connected together through reactances. In this manner a current may be obtained which is almost perfectly continuous.

**277. When mercury-vapor rectifiers are employed for supplying unidirectional current for arc lighting,** they require a special form of constant-current transformer provided with a double secondary winding, each portion of which is alternately active and inactive. The two parts of the secondary winding may be so arranged as to supply whatever sustaining reactance is required for satisfactory operation; this is the method adopted by one large company for one of its types of standard rectifier arc-lighting equipments. External reactance may also be supplied through suitable reactance coils; this method is used by another large company, and is also used by the first-mentioned company in another standard type of rectifier arc-lighting equipments.

**278. A fifty-light equipment** manufactured by the first-mentioned company (Par. **277**) makes use of the self-sustaining feature. In the regulator part of the equipment the secondary coils are placed at the top and the bottom of a shell-type core and are so designed as to give the required sustaining inductance, which is the same as the inductance obtained between the middle point of the two coils and the two outer terminals connected together. The primary winding is made up of two coils connected in series, and so arranged by means of wheels and counterweights that they will move in opposite directions from the middle point of the magnetic circuit; under full-load operating conditions they will be as far apart as possible. But under no-load conditions they will be at their minimum separation. In operation, both primary coils are repelled from the active secondary with equal force, but the mutual attraction due to their own currents makes the two coils tend to approach one another; so that with proper counterweights and adjustments, a constant alternating-current may be maintained in the primary, and thus a constant unidirectional-current may be obtained from the secondary. The general appearance of a rectifier equipment for series arc lighting is shown in Fig. 58.

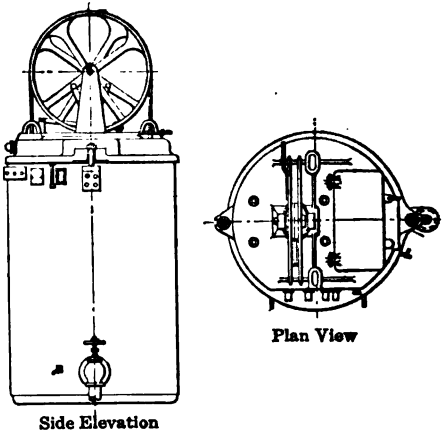

FIG. 58.

**279. A one-hundred-light equipment** manufactured by the same company (Par. **277**) has essentially two separate constant-current regulators, which have a common magnetic circuit. The primary coils are independent and are connected in multiple, so that each primary coil and the adjacent

Digitized by Google

secondary coil act as one independent regulator. The two circuits of fifty lamps each are insulated from one another.

**280. Rectifier equipments for charging electric vehicle batteries.** This apparatus may be automatic or non-automatic. The non-automatic equipment is not self-starting, and if the line voltage fails temporarily the rectifier will not start itself. The automatic equipment is self-starting, thus making it possible to charge batteries at night, without attendance; furthermore, by means of inductance both in the supply circuit and the battery circuit, the current is automatically decreased as the charge proceeds. A time-switch may be provided to terminate the charge at some predetermined time; in case it is found that the charge is not complete, it can be completed in a comparatively short time when attendance is available. The rectifier is operated from an auto-transformer which is wound for a supply voltage of 100 or 220 volts. These equipments are manufactured in suitable sizes to charge from 10 to 24 cells and from 20 to 44 cells; a special equipment for charging Edison storage batteries has a capacity of 20 to 54 cells. Other equipments are manufactured for charging telephone storage batteries, ignition batteries, and for operating arc lamps for moving-picture machines.

**281. Mercury-vapor rectifiers for power service.** It may be confidently predicted that in a few years the mercury-vapor rectifier will largely supplement the synchronous converter for supplying direct-current for railway systems. A great deal of experimental work has been done with the object of developing rectifiers for heavy power service, but the work has not yet advanced far enough to permit of the publication of any data as to size, ratings, etc.

## ELECTROLYTIC RECTIFIERS*

**282. Theory of operation.** It has been found that when a plate of aluminum and a plate of lead or carbon are immersed in certain solutions, an electric current can be made to pass in one direction, but not in a reverse direction. In other words, this combination will act as an **electric valve** and is the basis upon which the electrolytic rectifier and electrolytic lightning arresters are designed. The more complex the acid radical employed in the solution of the electrolyte, the more complete will be the valve action with a given voltage, or, in other words, the higher will be the voltage which may be satisfactorily rectified. In view of this fact, recent developments have been made in the use of ammonium phosphate or sodium borate dissolved in water, as the basis of the electrolyte.

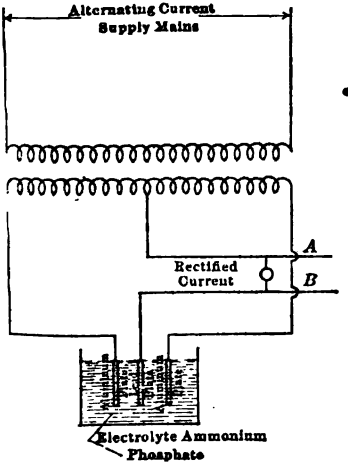

Fig. 59.—Diagram of electrolytic rectifier.

The electrolytic rectifier, therefore, consists essentially of two aluminum plates and a lead plate immersed in a solution of ammonium phosphate and connected to some transforming device, as shown in Fig. 59. Such an arrangement will allow the current to pass from the lead plate, but never from the aluminum plates, with the result that the current flowing between, the terminals marked A and B will be unidirectional, but pulsating.

**283. General characteristics.** Such a rectifier is comparatively cheap, simple to construct, requires no sustaining circuits, and to this extent is satisfactory for handling very small loads where the service is intermittent.

*See Sec. 19.

Digitized by Google

**284. The efficiency** of the rectifier is relatively low, seldom exceeding 60 per cent. and frequently averaging much less. The efficiency increases with decrease in the amount of current to be rectified.

**285. Heating.** Since the efficiency is low, the heat loss in the rectifier is comparatively large, which results in rapid deterioration of the plates. The degree of rectification, as the temperature rises, is much less complete. In other words, the leakage of current becomes excessive as the current increases, unless cooling means are provided.

**286. Treatment of plates.** A further objection to the electrolytic rectifier is the necessity for occasionally "treating" the plates to form the necessary insulating and rectifying films.

**287. General applications.** As a result of the low efficiency, the rapid deterioration, and the rapid heating of the electrolytic rectifier, it is seldom used for ordinary loads. Its present field appears to be limited to X-ray equipments and experimental purposes where a cheap rectifying device is required for light intermittent service.

**288. Artificially cooled electrodes.** Recent improvements have been made in electrolytic rectifiers which permit operation at higher current densities. One of these consists in cooling the aluminum cathode by a stream of water. The effect is such that a current ten times as large can be permitted with the cooled cell as with the same cell uncooled. An excellent rectifying effect with a cooled cell may be obtained with frequencies as high as 4,000 to 10,000 cycles per second.*

## MECHANICAL RECTIFIERS

**289. The vibrating type of alternating-current rectifier** is a simple, efficient and inexpensive piece of apparatus adapted particularly to the charging of three-cell vehicle batteries.

**290. General characteristics of vibrating type of rectifier.** It is essentially an electrically operated vibrating switch which reverses the connection of the alternating-current line to the battery in synchronism with the alternations of the current, this reversing action being accomplished at the moment when the current flow is zero. There is therefore very little sparking at the contacts and the current delivered is unidirectional and pulsating.

**291. The principle on which the vibrating rectifier operates is as** follows: a small transformer serves to reduce the alternating-current line voltage to a suitable value; two alternating-current magnets are connected across one-half of the low-voltage winding and are so arranged as to present at any instant poles of like polarity before those of a steel magnet which is excited from the battery. Hence during one-half cycle of the alternating current, one of the poles of the pivoted magnet will be attracted and the other repelled, and the opposite action will take place during the other half-cycle. The pivoted magnet is connected to one terminal of the battery and the other terminal of the latter is connected to the middle point of the low-tension winding of the transformer. Two platinum contacts carried on the pivoted magnet are thereby brought alternately in contact with two other contacts connected to the low-voltage terminals of the transformer, as shown in Fig. 76. It is of no importance which terminals of the battery are connected to the binding posts of the apparatus, since the winding of the pivoted magnet automatically determines the proper polarity of the binding posts.

**292. Sparking.** A properly designed vibrating rectifier should operate without sparking, otherwise the life of contacts will be short. To secure sparkless operation, contact should be broken at the instant the current falls to zero and should be made again at the moment the instantaneous value of the alternating voltage wave is equal to the e.m.f. of the storage battery. If contact is broken before the current reaches zero and made again some time after the alternating e.m.f. has reached the proper value, the maximum input to the battery will not be obtained; on the other hand, if the current reverses before contact is broken, part of the battery charge will be dissipated in the circuit.

When the wave-form of the alternating-current supply differs from a sine-wave it may be necessary to change the adjustment slightly to prevent

* See *Elek. Zeit.*, Aug. 21, 1913. *Phys. Zeit.*, June 15, 1913.

Digitized by Google

**sparking.** This may be accomplished by means of a variable resistance in series with the alternating-current magnets, which permits the time-phase lag of the magnetizing current behind the secondary e.m.f. to be adjusted until sparkless operation is obtained.

**293. Commercial types.** Several forms of this type of rectifier are on the market; they differ in structural details, but the principle of operation is much the same in all. Some of them make use of only one-half the alternating-current wave; since only a portion of each half-wave can be used, such a method of operation is inefficient and necessarily means a heavier and more bulky piece of apparatus for the same work.

**294. Ratings and efficiency.** The efficiency is usually about 55 per cent. Commercial types are made for operation on 60, 50, 40, or 25 cycles, at 110 volts. They are designed to charge 3 cells of storage battery and deliver a current of from 8 to 8.5 amp.

**295. Other forms of mechanical rectifiers.** Mechanical synchronous contactors are used for rectifying alternating-current waves so that direct-current galvanometers may be employed for precise and delicate measurements on alternating-current circuits. Since it is essential in such cases to reverse the contacts as quickly as possible, so that as much as possible of the alternating waves shall be rectified, these devices are costly and require a great deal of care in their design. Some high-voltage contact rectifiers have also been devised for laboratory work (Sec. 3).

## SYNCHRONOUS MACHINES

### GENERAL

**1. Definition.** A synchronous generator (or motor) usually consists of a system of alternately north and south magnetic poles, comprising the field, which moves with respect to a system of suitably connected conductors in which the alternating e.m.f. is induced. These conductors together with their mounting are called the armature. See Fig. 1. The magnetic poles of the field are usually excited with direct-current supplied by a separate generator called an **exciter**. See Par. **9**.

FIG. 1.—A portion of the armature and field of a synchronous machine.

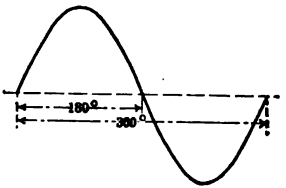

FIG. 2.—A graph of a cycle of e.m.f.

**2. The "cycle."** In the ordinary heteropolar alternator, the e.m.f. induced in each armature conductor reverses with the passage of each pole, *i.e.*, for a peripheral movement equal to one pole pitch (the peripheral distance between the centres of adjacent poles). The set of values comprised within a double reversal, or corresponding to a movement equal to twice the pole pitch, repeats itself indefinitely, and is called a cycle of values, or simply a cycle. See Fig. 2. The graph of these values plotted against time in rectangular coordinates, is referred to as the **e.m.f. wave** of the machine in question.

**3. Frequency.** The time required for the execution of a cycle is called the **period** of the alternating e.m.f., and the number of cycles per second is called the frequency. Frequency, $f$, is expressed by the relation: $f = p \times$ rev. per second, where $2p$ is the number of poles. Modern commercial frequencies in the United States are 60 and 25 cycles per sec.

**4. Electrical and magnetic degrees.** It is customary to refer to a cycle as 360 electrical degrees (see Fig. 2), or one electrical revolution, and to the circumferential distance from the centre of one pole to that of the next

Digitized by Google

**pole** *of the same polarity*, as 360 magnetic degrees. Thus two active armature conductors displaced from each other by $\beta$ magnetic degrees will experience e.m.fs. differing in phase by $\beta$ electrical degrees. Two active conductors 180 magnetic degrees apart would naturally be connected in series to form a loop or coil, since their two e.m.fs. will then be always in the same direction around the circuit of the loop (see coils I and II, Fig. 3).

**5. The two-phase (quarter-phase) alternator.** Referring to Fig. 3, coils I and II are displaced from each other by 90 magnetic degrees. The

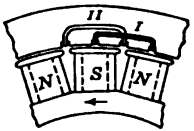

FIG. 3.—Part of the armature and field of a quarter-phase alternator.

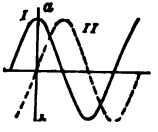

FIG. 4.—Graph of the electromotive forces in a quarter-phase alternator, plotted against time.

e.m.fs. induced in these two coils therefore differ in phase by 90 deg. If all coils in the same phase as I, are connected in series, and all those in the same phase as II in another series, the two circuits being separate and distinct electrically, the machine is called a two-phase machine. The circuits themselves are referred to as the two phases or phase windings of the machine. Sometimes this type of machine is called a quarter-phase machine, since its two e.m.fs. differ in phase by 90 deg. or one-quarter cycle. The electromotive force in coil I is zero when that in coil II is a maximum, and *vice versa*. If the value of the electromotive force from instant to instant is a sine function of the relative angular position of the armature coils and revolving field, the curves of the electromotive forces in coils I and II, may be plotted as indicated in Fig. 4, in which the ordinates represent the instantaneous values of the electromotive force, and the abscissas represent time. The four terminals of the two windings of a two-phase alternator are usually brought out to the terminal board. The load may be fed by three wires, one the common return for the other two, or four wires may be employed as two independent circuits.

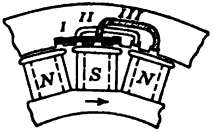

FIG. 5.—Part of the armature and field of a three-phase alternator.

**6. The three-phase alternator.** If three sets of overlapping coils displaced by 60 magnetic degrees (Fig. 5) be connected to three separate cir-

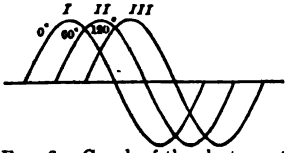

FIG. 6.—Graph of the electromotive forces in the three armature circuits of a three-phase alternator.

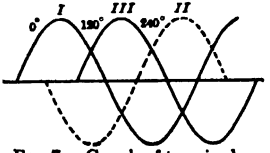

FIG. 7.—Graph of terminal pressures in the three phases of a three-phase alternator.

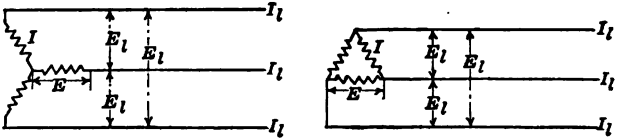
cuits, their e.m.fs. will differ in phase by 60 deg. (see Fig. 6). By reversing the terminal connections of phase II, we reverse the phase of its e.m.f. with respect to the load and obtain the three voltages shown in Fig. 7. These voltages differ in phase by 120 deg. The difference between the three e.m.fs. of Fig. 6 and those of Fig. 7 is obviously external to the machine in which they are generated, which is called a three-phase alternator. In many three-phase

Digitized by Google

alternators the phases are internally connected, with only three terminals brought out. There are two principal methods of making these connections, Y and Δ (see Figs. 8 and 9). Let $E$ and $I$ represent respectively, volts and amperes per armature phase; and $E_l$ and $I_l$ the line volts and amperes. Then, in the Y armature, $E_l = E\sqrt{3}$, and $I_l = I$; and in the Δ armature, $E_l = E$, and $I_l = \sqrt{3}\, I$. Therefore the power in each case will be $3EI \cos \theta = \sqrt{3}\, E_l I_l \cos \theta$, where $\theta$ is the common phase difference between the voltage and current of each phase, balanced load assumed.



FIGS. 8 AND 9.—Internal and external e.m.fs. and currents in three-phase alternators with Y and Δ connections.

**7. Note on phase classification.** There is a slight inconsistency in the usual classification of alternators and systems. In the ordinary three-phase alternator (Fig. 5) there are, in each 360 magnetic degrees of circumference, six coil groups or belts of conductors. In these groups are being generated six different e.m.fs. differing in phase progressively by 60 deg. or one-sixth of a cycle. If the six terminals of the three phases be connected to three equal loads, the six currents in the six leads, when counted positive in the same direction along the line, will differ in phase progressively by 60 deg. If, however, the three phases be connected in Y or Δ, with three leads connected to the load, the three currents, counted positive in the same direction along the line, will differ in phase by 120 deg. or one-third of a cycle. To be consistent these two systems should be referred to as "six-phase" and "three-phase" respectively, although the alternator is the same. Moreover when a closed-coil armature is used for alternating e.m.f. generation, as in the case of a synchronous converter, it is called "three phase" when it has three 120-deg. taps and three phase-belts of 120-deg. span, and six phase when it has six 60-deg. taps and six phase-belts each of 60-deg. span. Thus, to be consistent, the ordinary three-phase alternator should be called a six-phase alternator, although mostly used to supply three-phase circuits.

**8. Single-phase generators*** are occasionally required for railways and also for certain electrochemical and electrothermal processes. Most single-phase generators are simply Y-connected three-phase generators with one of the three legs left idle. When a generator is operated single-phase, it is important that the pole shoes should be fitted with a heavy amortisseur or squirrel cage winding to damp out the effects of the pulsating armature reaction (Par. 44). Furthermore it is important that all parts of the magnetic circuit shall be well laminated in order that pulsations in the resultant m.m.f. may not occasion excessive iron losses.

Occasionally single-phase generators are supplied with distinctly single-phase windings as shown diagrammatically in Figs. 10 and 11. The windings in these two figures differ from one another in the extent to which the conductors are distributed over the surface of the stator. The complete distribution employed in Fig. 11 is wasteful. The proportions of Fig. 10 are more nearly correct. (See Par. 28, Par. 31, and Fig. 32.) A single-phase generator for a given kv-a. output and a given power factor, voltage and speed, is inherently more heavy and expensive than the equivalent poly-phase generator by fully 65 per cent. Even then, if the speed is very high, as

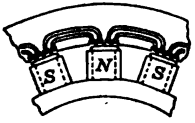
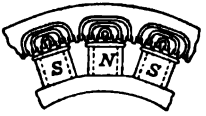
Digitized by Google

in the case of a steam turbine-driven generator, the temperature rise will be greater and its efficiency will be lower than in the case of the polyphase machine. Very few manufacturers of dynamo-electric machinery have realised the difficulties attending the design and construction of single-phase generators, and many faultily designed machines have been built. Singular as it may seem, there is even now a general failure to pay heed to these unsuccessful results. Even for cases where polyphase machines are required to carry differing loads and power-factors on the various phases, the heating may be decidedly excessive unless such machines are designed with due regard to the pulsating m.m.f. which will be present under these conditions of load.





FIGS. 10 AND 11.—Single-phase alternators with distinctly single-phase windings.

**9. Excitation:** Separate excitation is almost always employed in modern synchronous generators. The exciter is usually either mounted on an extension of the main generator shaft or driven by a motor from the generator bus. This is, however, objectionable in that a given percentage variation in the speed of the generator will occasion a greater percentage variation in its voltage. Thus if, for instance, the speed varies 1 per cent., the speed of the exciter will vary 1 per cent. and the voltage of the exciter by a little more than 1 per cent.; this causes a little more than 2 per cent. variation in the voltage of the main generator. It is, therefore, desirable that exciters be driven by independent prime movers whenever it is possible. Various methods have been devised for rendering alternators self-exciting but, except for comparatively small machines, these are never used.

**10. Relative motion: revolving armature and revolving field.** The revolving-armature type of alternator is now rarely employed even in very small sizes. Revolving-field alternators fall into two classes: (*a*) those with cylindrical rotors provided with windings embedded in slots in the surface; (*b*) those with salient-pole rotors. The former are now almost universally used for extra high-speed generators driven from steam turbines, owing to stronger mechanical construction, better balance, less noise and lower air friction (which last may represent a loss as great as the aggregate of all the others). For water-wheel generators and for generators driven by reciprocating engines the salient-pole construction is usually the most appropriate, although, for other than very low speeds, a good argument can usually be presented for the cylindrical type of rotor. The Lancashire Dynamo and Motor Co. of Manchester, England, have used the cylindrical type of rotor in a line of medium-speed synchronous motors. Their design is described on p. 90 of The Engineer for Jan. 24, 1913.

**11. Vertical and horizontal types.** Until recently a considerable proportion of the steam turbine-driven alternators were of the vertical type. The recent large increase of speeds of steam turbo-alternators (in many cases double) involving greater lengths, smaller diameters, and greater vibrational difficulties, has made more desirable the horizontal type with its inherently better provision for strength of frame and accessibility of parts. The vertical type is often used for low-speed water-wheel generators. As a notable instance of the vertical type may be mentioned the 30 Keokuk generators, each 9,000 kv-a., 25 cycles and 58 r.p.m. with 52 poles. The external diameter of the rotor is 25 ft. and it weighs 116 tons. The entire machine weighs some 275 tons.

Although little used, the umbrella type of revolving-field alternator (Fig. 13) inherently provides great fly-wheel effect.

**12. Belted type.** Although the use of the belt drive is gradually falling off, electrical manufactures still find it necessary to carry rather extensive lines of belt-driven alternators. In the larger sizes of belt-driven alternators, an outboard bearing is provided. In such cases sufficient space

Digitized by Google

is generally arranged between the two main bearings to permit of moving the stator longitudinally, in order to render the rotor accessible. In small machines, however, the bearings are fitted in the end shields. In this type and, in fact, in all types of two-bearing, belt-driven machines, the bearing at the pulley end should be of especially liberal proportions. In England, rope drive is much more usual than belt drive.

**13. Engine type.** (Direct-connected to reciprocating engines.) In this type sufficient momentum must be provided in the rotating element to ensure the required degree of uniformity in the angular velocity. Three arrangements to accomplish this end are: (a) a separate fly-wheel; (b) the fly-wheel as an integral part of an internal rotor, Fig. 12; (c) the fly-wheel as an integral part of an overhung rotor, Fig. 13.

In America the fly-wheel effect is expressed in terms of the $WR^2$ where the weight of the rotor in pounds is denoted by $W$, and the radius to the centre of gyration, in feet, is denoted by $R$. In countries employing the metric system, the fly-wheel effect is expressed in terms of the $GD^2$, where $D$ is the diameter at the centre of gyration in meters, and $G$ is the weight of the rotor in kilograms. The greater the weight of the required fly-wheel, the more liberal must be the design of the bearings.

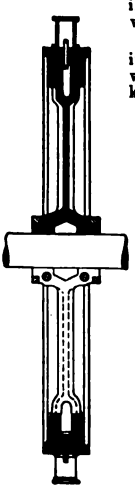


FIG. 12.—Fly-wheel rotor for alternator.

**14. Water-wheel type** alternators have speeds ranging widely in accordance with the head of water under which the prime movers operate. The Keokuk 9,000-kv-a. generator (Par. 11) has a rotative speed of 58 rev.

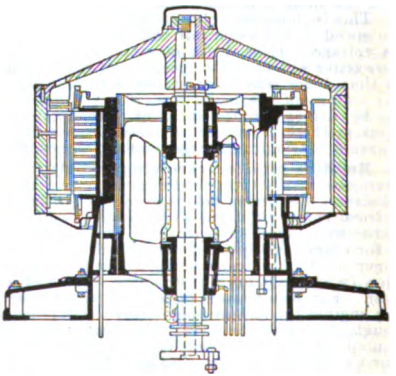

FIG. 13.—Umbrella type of revolving-field alternator.

per min., and the 5,000-kv-a. (Niagara) generator (Fig. 13) has a rotative speed of 250 rev. per min.

Even for the same head, water-wheels are built for any speed within quite a wide range. On the whole, the water-wheel will be lower in price and more efficient when constructed for a moderately low speed. On the other hand, the weight and cost of the generator will decrease with increasing rated speed, up to fairly high speeds. Consequently the most economical compromise will usually be at some intermediate speed. At all but very low heads, therefore, the tendency is toward fairly high speeds, though of course the speeds are far lower than for steam turbine-driven generators. For 5,000- to 10,000-kv-a. water-wheel sets, speeds of some 300 to 400 rev. per min. are now often employed. An additional reason for not resorting to much higher speeds is the necessity for providing in the design sufficient mechanical strength to ensure that the machine will safely withstand speeds approaching double the normal speeds, in the event of accident to governors or gates, see Standardisation Rules, Sec. 24. See also paper in Vol. XXXI of Trans.

Digitized by Google

A. I. E. E. by D. W. Mead entitled "The Runaway Speed of Water-wheels and its Effect on Connected Rotary Machinery." Water-wheel generators of both the horisontal and vertical types are built in sizes up to 15,000 kv-a. Fly-wheels are not usually supplied for water-wheel generating sets, owing to the uniform rotative effort of the water-wheels.

**15. Steam turbine-driven types.*** Extra high-speed generators are now almost invariably constructed with the cylindrical type of rotor carrying the field winding embedded in slots distributed over its surface. Owing to the great stresses associated with high peripheral speeds, the entire rotor (including the extensions constituting the shaft) is often made from a single piece of steel. In the largest machines, peripheral speeds of the order of 25,000 ft. per min. (127 meters per sec.) are employed. Bipolar 25-cycle designs are now under construction for rated loads of 25,000 and 30,000 kv-a. at a speed of 1,500 rev. per min. Bipolar 60-cycle designs for a speed of 3,600 rev. per min., have been built in sizes up to 5,000 kv-a.

It is characteristic of extra high-speed alternators of great capacity that since they are so exceedingly small for their output they can only be maintained at appropriately low temperatures when in operation, by circulating through them enormous quantities of air. For this purpose, and also in order to ensure reasonable absence of noise in their neighborhood, such generators are of the completely enclosed type with definite inlets and outlets for the circulating air. These subjects are discussed in Par. **129** to **139**.

## ARMATURE WINDING

**16. Considerations affecting the choice of armature winding** for an alternator. (a) Efficient e.m.f. generation, *i.e.*, without considerable differential generation in series-connected conductors. This indicates coils whose pitch or span is about 180 deg. The pitch is on other accounts sometimes as low as 0.66 or even 0.50. (b) Wave shape. In most cases an approximate sine-wave is desired, which ordinarily means a distributed winding (several slots per pole per phase). It is not necessary to have a whole number of slots per pole per phase. In fact a fractional number is sometimes desirable, *e.g.*, a machine with 1½ slots per pole per phase will have as good a wave shape, other things being equal, as a machine with five slots per pole per phase. Wave shape also usually indicates a fractional-pitch winding (Par. **20**), *i.e.*, coils with a pitch less than 180 deg. (c) From the standpoint of heat-dissipation, as well as of wave shape, the winding should be distributed rather than concentrated; this also reduces the leakage reactance slightly. On the other hand, much distribution means more insulation space and less slot space for copper, particularly in high-voltage machines. (d) From the standpoint of first cost it is important that the coils shall be wound and insulated before being placed in the machines, also that they shall be of one shape rather than of many shapes. This involves the necessity of open slots, although magnetic wedges are sometimes inserted after the winding is in place, in order to secure the advantages of closed or partly closed slots.

**17. Classifications of armature windings:** (a) coil-end classification (spiral or lap; one range, two range, three range or barrel); (b) according to the number of layers (one or two); (c) according to the pitch of the coils; (d) open slots (usually with form wound coils) or closed slots; (e) according to the number of slots per pole per phase; (f) according to the number of circuits in each phase; (g) according to the number of phases; (h) in three-phase windings, *Y* or Δ connection.

Diagrammatic illustrations of three-phase windings are shown in Fig. 14 which explains itself. All of these illustrations are for **single-layer wind-**

Digitized by Google

**ings**, such that they can be wound with one coil-side per slot. It will be observed also that, in effect, they are all **full-pitch windings**, *i.e.*, that the two groups of active conductors belonging to any given phase and lying under adjacent poles are always 180 deg. apart, as groups, although some individual coils of the spiral windings have a pitch less than 180 deg.

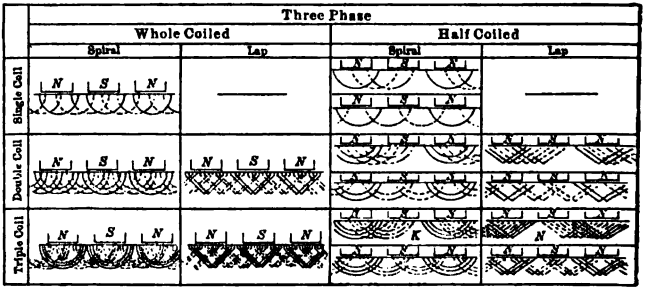

FIG. 14.—Three-phase windings.

**18. A three-phase spiral winding** with three slots per pole per phase is shown in Fig. 15, and a two-phase spiral winding with six slots per pole per phase in Fig. 16. For obvious reasons these are sometimes called **chain windings.** They are also **two-range windings**, *i.e.*, the coils extend outward in two ranges, or rows. Fig. 5 shows part of a **three-range winding.**

**19. Two-layer lap winding.** A more common type than any of the windings mentioned in Par. **18**, is the two-layer lap winding, shown in Fig. 17. This type has the advantage not only of a single shape of coil, but also that the coil pitch may be any whole number of slots, without disturbing the symmetry of the winding.

FIG. 15.—Three-phase, spiral, two-range winding.

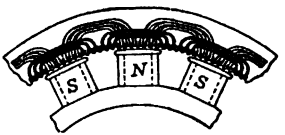

FIG. 16.—Quarter-phase, spiral, two-range winding.

**20. Fractional-pitch winding.** When the coil pitch is less than 180 deg., the winding is called a fractional-pitch winding. Fractional-pitch windings are much used not only because of their effect on the wave shape (Par. **25** et seq.), but also because of the saving in coil-end copper and in over-all length of machine. The gain is particularly noticeable on two-pole machines where fractional pitch is practically universal. It is also possible with this type of winding to have a fractional number of slots per pole, which tends to eliminate tooth harmonics from the e.m.f. wave. The end connections of the two-layer lap winding stand out in a single range, but because of its appearance and continuity it is often called a **barrel winding.** Figs. 17 and 18 show samples of three-phase, two-layer lap windings with full pitch and 50 per cent. pitch respectively. The between-coil connections and phase terminals, are shown for only one phase. All things considered, the two-layer lap winding is the most flexible and generally useful type. In very high-voltage machines, the necessity for insulation between the two layers is an objection, particularly with fractional pitch, when there is a relatively large potential difference between the two coil-sides in a slot.

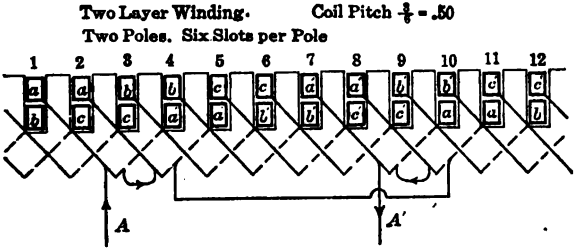

FIG. 18.—Three-phase two-layer lap winding with five-tenths pitch.

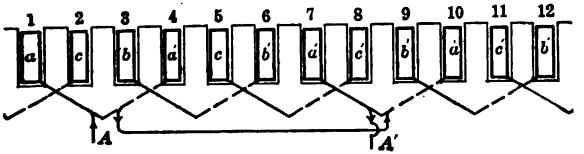

FIG. 19.—Three-phase single-layer lap winding with five-tenths pitch.

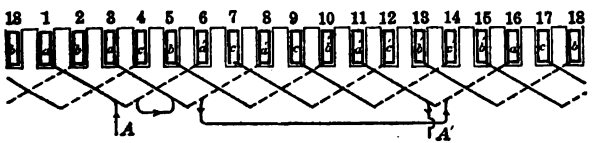

FIG. 20.—Three-phase single-layer lap winding with five-ninths pitch.

Digitized by Google

**21. Fractional pitch single-layer lap winding.** It is also possible to have fractional-pitch coils with a one-layer lap winding, but here the number of combinations is quite limited, see Figs. 19 and 20. Inter-coil connections are shown for only one phase. Fractional-pitch one-layer polyphase windings have the serious fault that in a certain portion of the slots, the phases alternate with one another, causing a very unfavorable distribution of the m.m.f. of armature reaction. Thus with three phases *A*, *B*, and *C*, four slots per pole per phase, and 75 per cent. pitch, the distribution of the phases in successive slots is as follows: *ACAABABBCBCCACAABABB*, etc. When each slot contains conductors of only one phase, the m.m.f. distribution is very unfavorable, but with a two-layer winding with four slots per pole per phase, and the same coil pitch, we obtain the following arrangement:

$$\left\{\begin{matrix} AAAABBBBCCCCAA \\ CCCAAAABBBBCCC \end{matrix}\right\} \text{etc.}$$

This arrangement provides a nearly sinusoidal distribution of the m.m.f.

**22. Multi-circuit windings.** Another classification of windings is according to the number of similar circuits in each phase; *e.g.*, a two-circuit 220-volt alternator could be changed to a single circuit 440-volt machine by series-connecting the two parallel circuits.

In three-phase alternators there is still another distinction, namely, between *Y* and Δ connection of the three phases.

## E.M.F. GENERATION

**23. Electromagnetic induction.** The law of electromagnetically induced e.m.f. may be stated in two ways: (a) whenever a conductor cuts a magnetic flux, an e.m.f. is induced which is proportional to the rate of cutting, *i.e.*, to the flux cut per sec.; (b) whenever the flux linked with a loop or coil of wire, changes for any reason, an e.m.f. is induced in the loop or coil, proportional to the rate of change of the flux and to the number of turns in the coil. For all ordinary cases, statements (a) and (b) are exactly equivalent. For the consideration of alternator electromotive forces, statement (a) will ordinarily be found the more convenient.

**24. E.m.f. formulæ.** Let $l$ = gross length of armature core, inches. $v$ = peripheral velocity in ft. per sec. $\mathfrak{B}_1$ = maximum gap density (maxwells per sq. in.) of equivalent sine-wave. $e''$ = root-mean-square volts per in. of active conductor. $N$ = series-connected active conductors per phase (twice the number of turns per phase). $E$ = volts per phase. $k_b$ and $k_p$ are the differential factors, Par. **28** and **29**. Then

$$e'' = \frac{12}{\sqrt{2}} v\mathfrak{B}_1 10^{-8} = 8.5 v\mathfrak{B}_1 10^{-8} \qquad \text{(volts)} \qquad (1)$$

and

$$E = k_b k_p e'' Nl = 8.5 k_b k_p v\mathfrak{B}_1 Nl 10^{-8} \qquad \text{(volts)} \qquad (2)$$

Another very common variety of the e.m.f. formula is obtained as follows: let $\Phi$ = flux per pole in maxwells; then the average e.m.f. per active conductor is $2f\Phi 10^{-8}$, and neglecting differential action, the average e.m.f. per phase is $2f\Phi N 10^{-8}$. To obtain the root-mean-square volts and at the same time to take account of the differential action, involves the form factor ($k_f$ = ratio of root-mean-square to average volts), and the differential factors, giving for the induced volts

$$E = 2k_f k_b k_p f\Phi N 10^{-8} \qquad (3)$$

The three $k$'s are usually combined in a single term $K$ which has an average value of 1.05 for full-pitch windings.

**25. E.m.f. wave shape.** Assuming constant speed, the e.m.f. generated by a single active armature conductor, or by a group of series-connected conductors making up a coil side and lying in a single slot, is proportional at each instant to the density of the magnetic flux through which it is cutting, and when plotted in rectangular coordinates will have the same shape as the "**field form**," *i.e.*, the curve showing the peripheral distribution of flux entering the armature from the field poles (see Par. **22** and **23**). This will be referred to as the elementary or slot e.m.f. It is an alternating e.m.f.

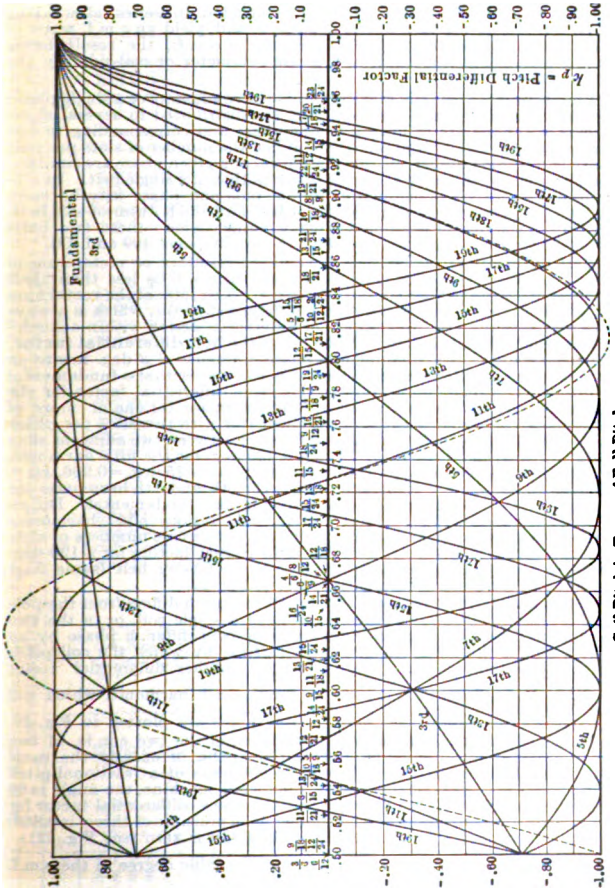

FIG. 22.—Curves of pitch differential factors.

Digitized by Google

but usually not sinusoidal, see Fig. 21. The no-load wave-shape of the machine is then obtained by adding together the e.m.fs. of the series-connected coil sides. This is very tedious as it involves the point-by-point addition of several dephased non-sinusoidal waves. An approximation of some kind is usually employed. The most satisfactory method of handling this problem is as follows: Analyse the field form or slot e.m.f. into its fundamental and harmonics; compound or add vectorially in their proper phase relation, the fundamentals of the several series-connected conductors or coil-sides, to obtain the fundamental of the resultant e.m.f.; and compound similarly the harmonics of each order to obtain the resultant harmonic of that order. To this end the armature conductors are grouped as follows.

**26. Similars.** Any number of conductors or coil sides, 180 magnetic degrees apart (generally called similars), connected in series, alternating right and left across the face of the armature, will yield an e.m.f. wave of the same shape as that of the field form or slot e.m.f., the result being simply the product of the e.m.f. of a single conductor or coil-side, by the number in series.

**27. Phase-belt.** In nearly all alternators the conductors of a single phase are not confined to one slot per pole, but are distributed in several slots. The group of conductors belonging to one phase and corresponding to one pole, will be referred to as a phase belt. When the number of slots per pole per phase is a whole number, all the phase belts of a given phase are similars, and the phase e.m.f. will have the same shape as that of a single belt. In a 2-layer winding the group of conductors for one pole and phase may be more conveniently separated into the top-of-slot belt and the bottom-of-slot belt, particularly in the case of fractional pitch windings where these two belts are displaced circumferentially. See Fig. 78 and 79, pages 499 and 500.

**28. Belt differential factor.** In general the resultant or vector sum of the e.m.fs. of the several coil-sides in a given belt will be less than their numerical sum, owing to their phase differences. The ratio of the vector sum to the numerical sum will be called the differential factor, which is always equal to or less than one. In the case of differential action within a single-phase belt, the differential factor will be called the **belt differential factor**, $k_b$. Remembering that a fundamental phase difference of $\beta$ deg. means an $n$th harmonic phase difference of $n\beta$ deg., it is easy to see that a fundamental phase difference which affords a relatively large differential factor for the fundamental, may give a very small differential factor for one or more of the harmonics. Thus, in a three-phase alternator with two slots per phase per pole, or six slots per pole, the phase difference between two adjacent slots is 30 deg. for the fundamental, $5 \times 30$ deg. $= 150$ deg. for the fifth harmonic, etc. The belt differential factors will then be $k_{b1} = \cos 15$ deg. $= 0.966$, $k_{b5} = \cos 75$ deg. $= 0.259$, $k_{b7} = -0.259$, etc. Thus the 5th and 7th harmonics are greatly reduced without appreciably reducing the fundamental. Differential factors for the fundamental and for the various odd* harmonics up to the 27th, for 60-deg. and 90-deg. belts and for various numbers of slots per pole are given in Table I, Par. 31. Differential factors for a 120-deg. belt may be obtained by multiplying those of the 60-deg. belt (same $N_{sp}$) by the 66⅔ per cent. pitch differential factors, Fig. 22.

**29. Pitch differential factor.** When the coil pitch differs from the pole pitch, the e.m.fs. developed in the two sides of a single coil, or in the two series-connected belts of a phase-group of coils, will differ in phase by an angle $\beta$, which is the angle (in magnetic degrees) by which the coil pitch differs from the pole pitch. This introduces another differential factor $\left(\cos \frac{\beta}{2}\right)$ for the fundamental and $\cos \frac{m\beta}{2}$ for the $m$th harmonic, which will be called the pitch differential factor. Its values are plotted in Fig. 22.

**30. Phase differential factor.** The addition of the two e.m.fs. of two phases of an alternator, involves differential action of exactly the same kind as that between the two series-connected belts of a fractional-pitch winding (Par. 29). In a three-phase $Y$-connected machine, the angle is 60 deg., which is equivalent to a ⅔ pitch; and the phase differential factor for the fundamental and for all the odd harmonics not a multiple of three, is 0.866; while for the harmonics which are multiples of 3, it is zero (see Fig. 22).

* Even harmonics are not present in any appreciable degree in the e.m.f. waves of commercial alternators.

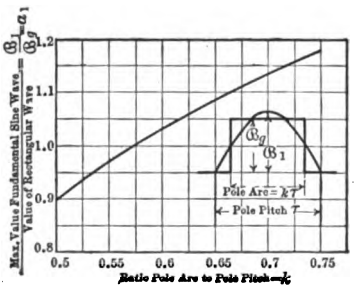

FIG. 23.

**By a suitable combination of belt, pitch, and phase-differential action, any harmonics present in the field form may be practically ironed out of the terminal e.m.f. leaving only a sine-wave which is the resultant of the fundamentals of the e.m.fs. in all the series connected conductors.**

**32. Field form of salient-pole alternators.** Neglecting the fringing of flux at the pole corners and assuming a uniform air-gap under all parts of the pole, the field form will be rectangular (see Fig. 23). The fundamental sine-wave of this field form has a maximum value: $\mathfrak{B}_1 = 1.27 \cos \pi/2\,(1-k)\,\mathfrak{B}_g = \alpha_1 \mathfrak{B}_g$. Values of $\alpha_1$ for various values of $k$ are given in Fig. 23. Fringing at the pole face edges will increase $\alpha_1$ and chamfering the pole face will decrease $\alpha_1$ slightly, $\mathfrak{B}_g$ being the actual gap density at the centre of the pole face.

Fig. 24 gives the harmonics (up to the 19th) of these rectangular field forms, plotted against $k$, in terms of the fundamental. The fringing will in most cases eliminate the higher of these harmonics, and considerably change the magnitude of the lower ones, usually reducing them. Thus Fig. 24 gives only a rough idea of the upper limits of the lower harmonics in the case of a uniform air-gap. If the pole face is shaped, these values may be still farther reduced. Three actual and quite different field forms are shown in Figs. 25, 26 and 27, and their harmonic analyses given below:

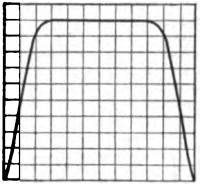

FIG. 27.—Observed field form.

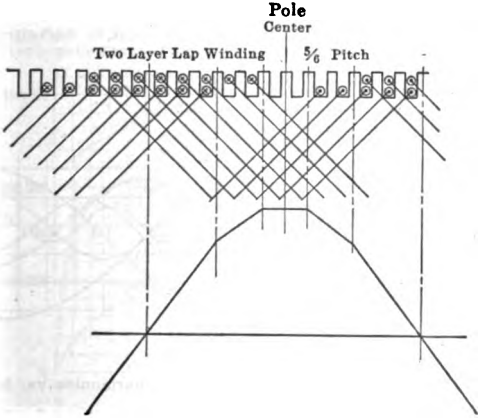
**33. Field form of distributed-field windings.** With distributed-field windings, the field form may be more easily controlled. Fig. 28 shows



FIGS. 28 and 29.—Distributed field winding with resulting field form, effect of slots neglected.

a two-layer distributed field winding with the top-slot layer displaced 2 slots from the bottom-slot layer. This is a simple lap-winding with a 120-deg. belt, a ⅚ pitch, and 12 slots per pole. The empty slots at the

Digitized by Google

centre of each pole could be filled with iron if desired. Neglecting the effect of slot openings and assuming that the current is distributed uniformly over each belt, the magnetic potential differences (ampere-turns) across the air gap, and therefore the field form, is shown in Fig. 29.

A simple manner in which to obtain the equivalent sine-wave of such a field form is as follows: Any such distributed field winding may be considered as made up of pairs of conductors, the two in each pair being 180 deg. apart. Consider the m.m.f. of a single pair. The field form of the pair if acting alone will be a rectangle, Fig. 30, of which the fundamental sine-wave has a maximum value, $A_1 = 4A \div \pi$. The 3rd harmonic has $\frac{1}{3}$ of this amplitude, the 5th, $\frac{1}{5}$, etc. Assuming that the resultant of the overlapping rectangular m.m.f. and flux distributions of the several pairs of conductors into which the winding has been artificially subdivided, is a curve whose harmonics are small and easily ironed out of the e.m.f. by the differential actions of the winding (*i.e.*, assuming a final sine-wave of e.m.f.); it is obviously unnecessary to consider anything but the *fundamental* of each rectangular field

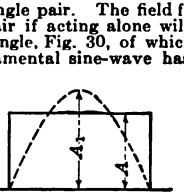


FIG. 30.—Field form of single 180-deg. loop, with its fundamental.

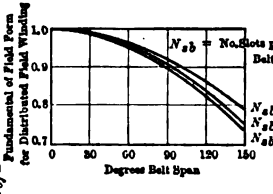

FIG. 31.—Belt differential factor for m.m.f. of distributed field windings.

form (Fig. 30), and to compound or add together the various fundamentals, which can be done geometrically, exactly as with the fundamentals of the e.m.fs. in the several conductors. It is thus possible to use the same differential factors as for the e.m.fs., except that the belt of conductors or of pairs of conductors is no longer confined to the definite widths of 60 deg., 90 deg., or 120 deg., although usually within these limits. The belt differential factor $k_b$ for the fundamental, is given in Fig. 31 for various numbers

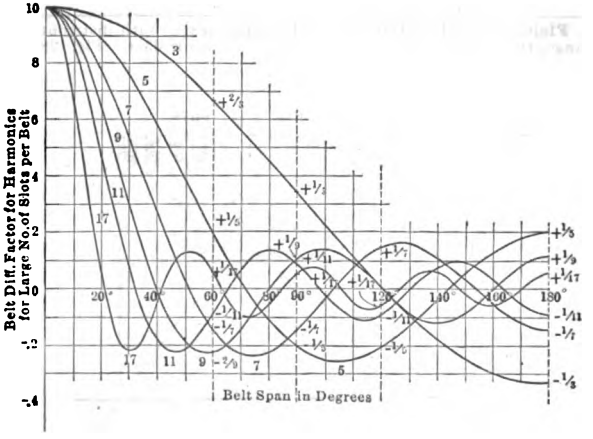

FIG. 32.—Curves of belt differential factors for harmonics vs. belt span.

Digitized by Google

of slots per belt, plotted against the belt span in degrees. Fig. 32 gives the belt differential factor of the harmonics for the case of a large number of slots per belt.

If $Ni_b$ = the ampere-turns per belt, or per pole, and if $K_2$ = ratio of gap ampere-turns to the total (including ampere-turns in the iron part of the circuit), the ampere-turns consumed in the single gap at the crest of the wave of magnetic p.d. across the gap is

$$Ni_g = \frac{2}{\pi} k_{bf} k_p K_2 Ni_b \qquad \text{(amp-turns)} \qquad (4)$$

where $k_{bf}$ is from Fig. 31 and $k_p$ from Fig. 22.

If $\delta$ be the air gap (inches) and $K_1$ the contraction factor due to slot opening, (Par. 40), the crest value of the equivalent sine-wave of gap flux density is

$$\mathfrak{G}_1 = 3.2\, K_1 Ni_g \div \delta = 2.03\, k_{bf} k_p K_1 K_2 Ni_b \qquad (5)$$

It is thus possible to produce a substantially sinusoidal distribution of magnetic potential difference across the gap, and therefore of flux density in the gap, when the gap is uniform. If the teeth are highly saturated the field form will be flattened somewhat as compared with the m.m.f. curve.

**34. Tooth kinks.** The field forms of Figs. 21, 25, 26, 27 are drawn as if there were no slot openings. Strictly speaking, they are therefore the equivalent smooth-core field forms, but are usually referred to simply as the field form. The presence of slot openings introduces flux pulsations, and kinks in the slot e.m.f. If there are 12 slots per pair of poles, there will result an eleventh and a thirteenth harmonic; if 24 slots, a 23rd and 25th harmonic, etc.

In machines with a few large slots these tooth kinks sometimes dominate the wave shape. They may be largely eliminated by the choice of a fractional number of slots per pole, so that the kinks will occur in different directions in different parts of the winding at the same instant. Sometimes this end is accomplished by the addition of one dead slot. The extra slot is then called a hunting slot. An uneven spacing of the poles accomplishes the same end in the same manner. In machines with a large number of slots per pole, small slot openings and a relatively long air gap, the presence of tooth kinks is not noticeable.

## THE MAGNETIC CIRCUIT

**35. Calculation of no-load saturation curve.** The saturation curve, or curve of terminal voltage at no-load, plotted against field ampere-turns, can

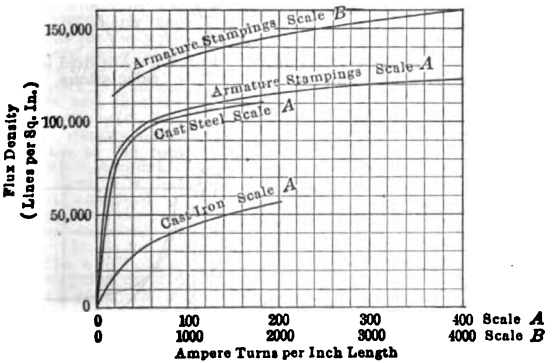

FIG. 33.—Magnetisation curves of average good iron and steel.

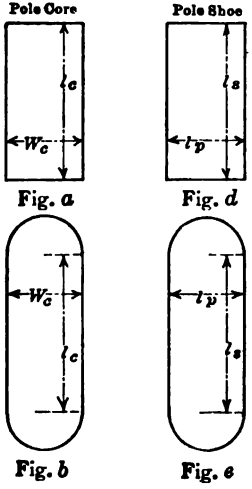
be computed ordinarily to within about 5 per cent., provided magnetization curves of the iron in the magnetic circuit are given. If these curves are not known for the particular iron, some such curves must be used as are shown in Fig. 33. Also see Sec. 4. A fairly rough approximation to the magnetic

Digitized by Google

qualities of the iron may not seriously affect the saturation curve, unless very high densities are used, since the reluctance of the iron portion is small as compared with the air-gap reluctance.



The reluctance of the magnetic circuit is ordinarily divided into five parts, air-gap, armature teeth, armature core, pole core, and yoke. For a given no-load terminal voltage ($E$), the flux per pole ($\Phi$) entering the armature, is determined by the equation $\Phi = (E \times 10^8)/(2k_f k_b k_p f N)$. See Par. **24**. To obtain the flux $\Phi_c$ in the pole core, the field leakage must be added, or $\Phi$ must be multiplied by the leakage coefficient $\nu$.

**36. Field leakage between salient poles.** The leakage coefficient ($\nu$) for salient poles is defined as the ratio of the maximum flux ($\Phi_c$) in the pole core, to the flux ($\Phi$) entering the armature from one pole. The difference between them is the leakage flux ($\Phi_l$).

$$\Phi_c = \Phi + \Phi_l \text{ and } \nu = \Phi_c/\Phi = (\Phi + \Phi_l)/\Phi = \frac{}{1 + (\Phi_l/\Phi)}$$

This leakage flux can be divided into two parts, that ($\Phi_{lc}$) which leaks be-

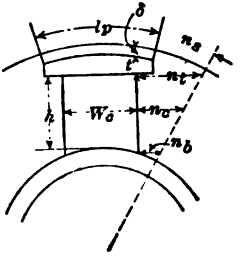


FIG. 34.—(*a*, *b*, *c*, *d* and *e*).—Diagrams for field leakage calculations.

FIG. 35.—For field leakage calculations.

Digitized by Google

tween the pole core and the cores of the adjacent poles, and that ($\Phi_{l_t}$) which leaks between the pole shoe and the shoes on the adjacent poles. Below are given formulæ for calculating $\Phi_l$, the total leakage flux from one pole, for rectangular (Fig. 34a), straight-sided with semicircular ends (Fig. 34b), and circular pole cores (Fig. 34c); and for rectangular (Fig. 34d), and straight-sided with semicircular ended pole shoes (Fig. 34e). Formulæ are given for both non-stepped (that is parallel-sided) field coils, and for stepped or tapering field coils. The notation is obvious from Fig. 35. $NI$ = the ampere-turns on one pole consumed in the gap, teeth and armature. The constants $k_1$, $k_2$, $f_1$, and $f_2$ are given in Figs. 36 and 37.

**37. Core leakage flux.**

| | |
|---|---|
| Rectangular (Fig. 34a) | $\Phi_{l_c} = (NI/1.59)h[(2l_c/n_c)+k_1]f_1$ for non-stepped coils. |
| | $\Phi_{l_c} = (NI/1.59)h[(2l_c/n_c)+k_1]f_2$ for stepped coils. |
| Straight-sided with semicircular ends (Fig. 34b) | $\Phi_{l_c} = (NI/1.59)h[(2l_c/n_c)+k_2]f_1$ for non-stepped coils. |
| | $\Phi_{l_c} = (NI/1.59)h[(2l_c/n_c)+k_2]f_2$ for stepped coils. |
| Circular (Fig. 34c) | $\Phi_{l_c} = (NI/1.59)hk_2f_1$ for non-stepped coils. |
| | $\Phi_{l_c} = (NI/1.59)hk_2f_2$ for stepped coils. |

**38. Shoe leakage flux.**

| | |
|---|---|
| Rectangular (Fig. 34d) | $\Phi_{l_t} = 1.255NI(t+\delta)[(2l_s/n_s)+k_1]$ |
| Straight-sided with semicircular ends (Fig. 34e) | $\Phi_{l_t} = 1.255NI(t+\delta)[(2l_s/n_s)+k_2]$ |

If $\Phi_l = \Phi_{l_c} + \Phi_{l_t}$ and $\Phi$ is the useful flux per pole, the leakage coefficient is $(\Phi+\Phi_l)/\Phi = \nu$. If $NI$ corresponds to $\Phi$ at no-load, $\nu$ is the no-load leakage coefficient $\nu_0$; if at full-load, $\nu$ is the full-load leakage coefficient, as explained in Par. 41.

**39. Flux densities in the iron, and required ampere-turns.** Dividing $\Phi_c$ by the cross-section of the pole-core, the flux density is obtained. The necessary ampere-turns to drive the flux through the pole are determined by finding from some such curve as that in Fig. 33, the ampere-turns per in. necessary for this density, and multiplying by the length of the pole core. Similarly the ampere-turns for the yoke may be determined, remembering that only one-half the yoke path is charged to one pole, and that the flux in the yoke is $(\Phi_c/2)$.

The tooth density varies from the tip to the root of the tooth. A roughly equivalent density is that at a point one-third of the distance from the narrow to the wide end of the tooth. If we let $k_3$ represent the width of the tooth at this point, divided by the tooth pitch, and if $q_{il}$ is the net iron length of the armature divided by the gross core length, the equivalent density to be used in computing ampere-turns for the teeth is that found by dividing the actual maximum density ($\mathfrak{B}_g$) in the gap by $k_3q_{il}$, and correcting by the curves in Fig. 38, which take account of the fact that all the flux does not enter the armature through the teeth, but that some of it passes through the slots.

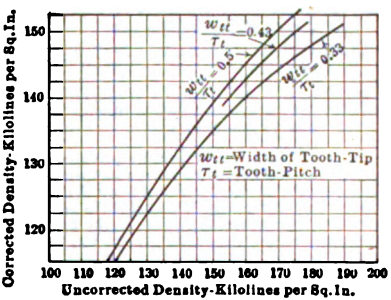

FIG. 38.—Curves for obtaining the corrected tooth density.

The density in the armature core varies from the centre of the pole to the point midway between the poles, but a good approximation is obtained by finding the density midway between the poles ($\Phi/2$ divided by the net iron cross-section of the armature core) and estimating an equivalent

Digitized by Google

length of path for this density. A considerable error in this item is evidently a very small part of the whole number of ampere-turns per pole.

For a non-salient pole machine the ampere-turns for the rotor can best be determined by finding the density midway between the poles, as for the armature core, and approximating to an equivalent length of path for this density. The rotor teeth may be treated exactly as the armature teeth.

A curve of terminal volts plotted against the necessary ampere-turns for the iron part of the magnetic circuit is called an **iron saturation curve.**

**40. Ampere-turns for air-gap.** If the armature were smooth-cored with no air-ducts, the cross-section of the air-gap would be the area of the pole face plus an allowance for fringing of the flux at the edges, and the actual density would be that determined by dividing the total flux per pole by this cross-section. This will be called the mean pole-face density. Since the flux is crowded into the teeth as it enters the armature, the density which must be used in computing the necessary ampere-turns is somewhat higher than the mean pole-face density.

The flux does not all enter the tips of the teeth, but fringes from the sides of the teeth, having the effect of increasing the width of the tooth tip ($w_{ti}$). This equivalent tooth-tip is given by the expression $w_{ti}+2\delta c_f$ where $c_f$ is the fringing constant and $\delta$ the length of the air-gap. Values of $c_f$ as a function of $w_{so}/\delta$ (the width of slot opening divided by the air-gap length) are shown in Fig. 39. If $\tau_t$ is the tooth-pitch, $a_s=(w_{ti}+2\delta c_f)/\tau_t$ is the fractional part of the tooth-pitch, which is effective as a flux path, or the fractional equivalent tooth-tip. Fig. 40 gives values of $a$ for various values of $k_{so}=w_{so}/\delta$ and $q_{so}=w_{so}/\tau_t$.

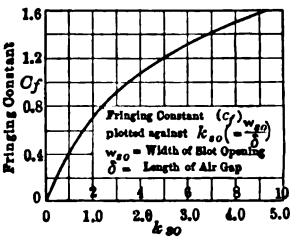

FIG. 39.—Curve for calculating air-gap reluctance.

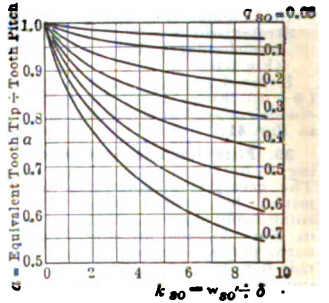

FIG. 40.—Slot contraction factor.

The peripheral-contraction factor $K_1$, or the ratio of effective peripheral surface to actual peripheral surface is equal to $a_s$ for a salient-pole machine, since there is contraction only on the armature side of the air-gap. For a slot-wound field one must determine the contraction factor both for the armature ($a_a$) and for the field ($a_f$). In this case $K_1=a_a a_f$.

The equivalent length of the armature core ($l_e$) is given by the expression $l_e=l+\delta-N_d(w_d-2c_f\delta)$ where $c_f$ is the fringing constant for the air-ducts, $N_d$ = number of ducts and $w_d$ = width of each duct. The longitudinal-contraction factor ($K_d$) is the fractional-equivalent armature length. It is $K_d=(l_e/l)$. The corrected gap density $\mathfrak{G}_{ge}$, upon which we must base our calculation of ampere-turns for the air-gap, is $\mathfrak{G}_{ge}=\mathfrak{G}_g/(K_1K_d)$, where $\mathfrak{G}_g$ is the mean density where the gap is shortest.

As explained in Par. **32** $\mathfrak{G}_g=\mathfrak{G}_1/a_1$, where $\mathfrak{G}_1$ is the maximum value of the equivalent fundamental sine-wave of flux under the pole, and $a_1$ is a constant depending upon the ratio of pole arc to pole pitch. Therefore $\mathfrak{G}_{ge}=\mathfrak{G}_g/(K_1K_d)=\mathfrak{G}_1/(a_1K_1K_d)$, and the necessary ampere-turns $Ni_g$ for the gap are given by the equation $Ni_g=0.3138\mathfrak{G}_{ge}$. Adding the value of $Ni_g$ to the number of ampere-turns per pole necessary to drive the flux through the iron parts of the magnetic circuit, we have the total number of ampere-turns per pole corresponding to the total flux $\Phi$, and therefore corresponding to the no-load voltage with which we began. This gives, therefore, one point on the no-load saturation curve. By taking values of voltage between

Digitized by Google

70 per cent. and 130 per cent. of the full-load terminal voltage, we shall obtain the saturation curve over a sufficient range for all calculations of regulation.

**41. No-load saturation curve with full-load leakage coefficient.** This may be determined as follows: In Fig. 41, curve $F_o$ is the no-load saturation curve of the machine in question, curve $Ni_{(f+y)}$ is the m.m.f. consumed in the field core and yoke. Assume that $F$ at full-load $= 1.4 \times F_o$ at no-load, see Par. 51. Assume also that the field leakage coefficient at no-load is $\nu_o = 1.3$. Then at full-load the leakage will be increased by 40 per cent., since it is proportional to the ampere-turns on the poles; and the full-load leakage coefficient will be $\nu_f = 1 + 0.3 \times 1.4 = 1.42$; i.e., the flux in the poles and yoke has increased from 1.3 to 1.42, or 9.2 per cent. The corresponding extra m.m.f. necessary will depend upon the shape of the curve $Ni_{(f+y)}$, and is designated $Ni_e$ in Fig. 41. Adding these extra ampere-turns to the no-load saturation curve, we obtain a point ($P$) on a curve of no-load volts plotted against ampere-turns for full-load leakage, or a no-load saturation curve with full-load leakage. It is obvious that a change in either phase or magnitude of the armature current will change the ratio ($F/F_o$), and thus the corresponding saturation curve, i.e., there corresponds such a load-leakage saturation curve for each load and power-factor, see Par. 51 et seq.

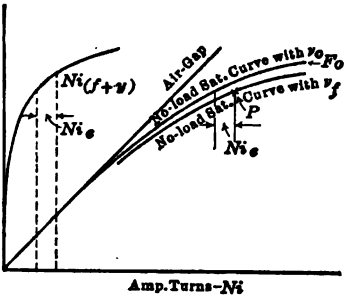

FIG. 41.—No-load saturation curve with full-load leakage, $\nu_f$.

**42. Table of average flux densities in magnetic circuit of alternators**

| | Frequency (cycles per sec.) | Flux density (lines per sq. in.) | |
|---|---|---|---|
| | | Ordinary steel | Silicon steel |
| Armature core | 25 | 60,000 to 70,000 | 70,000 to 80,000 |
| | 60 | 50,000 to 60,000 | 60,000 to 70,000 |
| Armature teeth | 25 | 100,000 to 120,000 | |
| | 60 | 90,000 to 110,000 | |
| Pole core | 95,000 to 110,000 lines per sq. in. for wrought-iron or steel poles. | | |
| Yoke* | Cast steel 90,000 to 100,000 lines per sq. in. | | |
| | Cast iron 30,000 to 35,000 lines per sq. in. | | |

## OPERATING CHARACTERISTICS OF SYNCHRONOUS ALTERNATORS

**43. Regulation.** The ratio of the difference between no-load and full-load terminal voltage to the latter is called the regulation, constant speed and full-load excitation assumed. Unless otherwise specified, unity power factor is assumed. The rise in voltage when the load is thrown off, or the drop when the load is applied, is chargeable to three causes: (a) armature reaction; (b) armature resistance;† (c) armature leakage reactance.

* The yoke density of a slow-speed machine is frequently lower than given above, as the yoke is made large in order to obtain fly-wheel effect.

† The resistance here employed should be larger (say 20 per cent.) than the ohmic resistance, to take account of the core losses due to the local or leakage flux, and eddy currents in armature conductors.

Digitized by Google

**44. Armature reaction.** The magnetic p.d. across the gap due to the armature m.m.f. may be considered as made up of two parts: (a) A sinusoidally distributed p.d., stationary with respect to the field poles; and (b) pulsating kinks due to the distribution of the armature current in belts and to its localization in slots. (b) is larger, the smaller the number of phases. Neglecting (b), the maximum or crest value of this equivalent sinusoidally distributed m.m.f. is

$$A_1 = 0.45\, k_b k_p \Delta\tau \qquad \text{(amp-turns)} \qquad (6)$$

where $\Delta$ = r.m.s. ampere conductors per in. of armature periphery, $\tau$ = the pole pitch in inches; $k_b$ = the belt differential factor, see Table I; Par. **31**; and $k_p$ = the pitch differential factor, see Fig. 22.

If the field m.m.f. were also sinusoidally distributed along the air-gap, it would be an easy matter to compound or add vectorially these two m.m.fs., in order to obtain their resultant. This is nearly enough the case for alternators with distributed field windings. In the case of salient-pole machines, the m.m.f. across the gap at no-load is practically constant at all points of the pole face, but in order to simplify their treatment, the equivalent sinusoidal m.m.f. distributions will be considered. This method results in considerable errors in some cases. The crest value of this equivalent sinusoidal distribution is

$$F_1 = a_1 F_g \qquad \text{(amp-turns)} \qquad (7)$$

where $a_1$ (Par. **32** and **33**, Fig. 30) is about 1.27 and $F_g$ is the constant magnetic potential difference (in ampere-turns) between armature core and pole core. With narrow or chamfered pole faces, $a_1$ will be slightly less. $F_g = K_2 F$, where $F$ is the total field ampere-turns per pole and $K_2$ a constant varying in different machines and with different fluxes. A rough average value of $K_2$ is 0.8, although in extreme cases it differs considerably from this value.

Eq. (6) holds for any number of phases; but for the case of the *single-phase* alternator, the alternating armature m.m.f. must be replaced by two half-value revolving m.m.fs., one forward and one backward with respect to the armature; or one stationary and the other at double frequency with respect to the field. Eq. 6 gives only that component which is stationary with respect to the field. The other component induces double frequency e.m.fs. and currents in the field coil, and reactive e.m.fs. in the armature. (In the balanced polyphase case the backward revolving components of the several phases cancel or neutralize each other.)

**45. Leakage reactance** is generally supposed to represent that part of the flux linked only with the armature conductors, but as a matter of fact the only such flux is some of that linked with the coil ends, since the whole effect of the armature m.m.f. in the vicinity of the air-gap is merely to distort the main flux. However, owing to the localization of the current in slots surrounded by magnetic material which moves with the slot currents, and owing to the grouping of the slots in phase belts which move relatively to the field, there are local flux pulsations which are best treated as if separate from the main flux, although as a matter of fact they are only pulsating distortions of the latter. Armature leakage reactance of an alternator is about as difficult to define as to compute. For most practical purposes the following method will give satisfactory results.

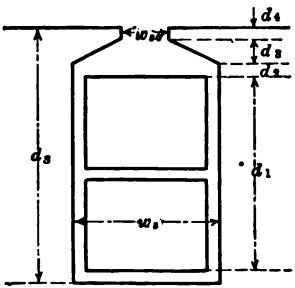

FIG. 42.—Slot section.

**46. Slot leakage** is the cross-slot flux, computed as if independent of the main flux. Referring to Fig. 42 the "inch permeance," or the flux linkage per amp-inch of slot, is

$$\varphi_s = 3.2\left(\tfrac{1}{3}\frac{d_1}{w_s} + \frac{d_2}{w_s} + \frac{2d_3}{w_s + w_{se}} + \frac{d_4}{w_{se}}\right) \qquad \text{(maxwells)} \qquad (8)$$

and the corresponding or slot reactance per phase is

$$x_s = 2\pi f\, k_p^2\, l N\, N_{ca}\, \varphi_s\, 10^{-8} \qquad \text{(ohms)} \qquad (9)$$

Digitized by Google

where $N_{ss}$ is the number of conductors per slot, $l$ the gross core length and $N$ the series-connected conductors per phase. The most convenient form in which to express reactance is as the *ratio of the reactance volts to the induced volts*. In this case it is—

$$q_{zs} = 0.74\varphi_s \tau_t \frac{k_p}{k_b}\frac{\Delta f}{v\mathfrak{B}_1} = 4.44 \frac{\varphi_s}{N_{sp}}\frac{k_p}{k_b}\frac{\Delta}{\mathfrak{B}_1} \qquad (10)$$

where $\tau_t$ is the tooth pitch in inches, $\Delta$ the root-mean-square ampere-conductors per in. of periphery, and $N_{sp}$ the number of slots per pole.

**47. Tooth-tip leakage.** This includes the flux that links with the slot conductors from tip to tip of tooth, sometimes by way of the interpolar air space, and sometimes across the air gap to pole face and back again. The effect of the presence of the pole face is usually neglected in making this calculation, since not only is the air gap long in the majority of alternators, but even were it not, the damping effect of the pole-face eddy currents would tremendously increase the apparent reluctance of the path through the iron of the pole face, with the result that it would approach the reluctance of air. In computing this flux, the integration is carried only to the centre of the tooth (see Fig. 43), since anything beyond this point would be chargeable to belt leakage. The flux linkage per ampere-inch of slot is—

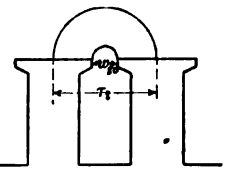

FIG. 43.—Tooth-tip leakage.

$$\varphi_{tt} = 3.2\left(0.3 + \frac{1}{\pi}\log_e\frac{\tau_t}{w_{so}}\right) = 0.96 + 2.35\log_{10}\frac{\tau_t}{w_{so}} \qquad (11)$$

and the per cent. tooth-tip reactance or *reactance ratio*, see Eq. 10, is—

$$q_{ztt} = 0.74\varphi_{tt}\tau_t \frac{k_p}{k_b}\frac{f\Delta}{v\mathfrak{B}_1} = 4.44 \frac{\varphi_{tt}}{N_{sp}}\frac{k_p}{k_b}\frac{\Delta}{\mathfrak{B}_1} \qquad (12)$$

**48. Belt leakage.** This covers the belt pulsations mentioned in Par. 44 (b). It is difficult to define or to compute this effect in terms of an equivalent leakage reactance, but the following method gives fairly satisfactory results. Compute the average mutual inductive effect of all the other slots in a given belt upon a given slot, by an extension of the tooth tip integration in circular paths to the edge of the belt. This is taken as a measure of the belt leakage. The equivalent flux linkage per ampere-inch of slot, for a full-pitch winding, is roughly,

$$\varphi_b = 0.7\ (N_{sb} - 1) \qquad (13)$$

where $N_{sb}$ = number of slots per belt.

Then since $N_{sb} = N_{sp}/p^1$, where $p^1$ = number of phases, the *belt-reactance ratio* is—

$$q_{zb} = 4.44\frac{\varphi_b}{N_{sb}}\frac{\Delta}{k_b\mathfrak{B}_1} = 3.3\left(\frac{1}{p^1} - \frac{1}{N_{sp}}\right)\frac{\Delta}{k_b\mathfrak{B}_1} \qquad (14)$$

for full pitch winding only. The effect of changing the pitch, on this element of leakage, is very marked, but not readily computed for the general case. The pitch factor $k_p$, as used when the slot is the unit, cannot be employed when the belt is the unit. Certain special cases may, however, be computed. Take for example the case of a five-sixths pitch in a three-phase winding; the three belts per pole are broken up into six equal belts with a pitch differential action in each belt. For the purposes of this computation there are now six phases and $q_{zb}$ will be reduced to considerably less than half of its full-pitch value. If $N_{sp} = 6$, $q_{zb}$ will be reduced to zero. If $N_{sp} = 12$, $q_{zb}$ will be reduced to one-third, and so on. For two-thirds pitch, however, the number of belts is not changed and the pitch factor $k_p$ applies directly.

Let $\varphi_s = \varphi_t + \varphi_{tt} + \varphi_b$ be *the total flux linkage per ampere-inch of slot*, then *the total leakage reactance volts of the slot-embedded active conductors*, in terms of the induced voltage, is

$$q_{zs} = 4.44\frac{\varphi_s}{N_{sp}}\frac{k_p}{k_b}\frac{\Delta}{\mathfrak{B}_1} \qquad (15)$$

and the corresponding reactance in ohms is

$$x_s = 2\pi f k_p^2 l N N_{ss}\varphi_s 10^{-8} \quad \text{(ohms)} \qquad (16)$$

Digitized by Google

For very hurried computations $\varphi_s$ is sometimes approximated without computation; it varies from 8 with shallow open slots to 15 with deep nearly closed slots.

**49. Coil-end leakage.** This computation is simplified by the fact that $\varphi_f$, the flux per ampere-inch of outside phase-belt-bundle, is nearly a constant quantity for full-pitch windings. Its values for all pitches of working range are given in Fig. 44.

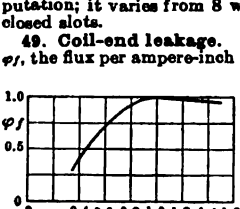

FIG. 44.—Curve of values of flux per ampere-inch for coil ends.

The coil-end reactance in ohms is then—

$$x_f = 2\pi f \varphi_f l_f \frac{N^2}{2p} 10^{-8} \quad \text{(ohms)} \quad (17)$$

where $l_f$ = the length of a single coil end, or the free length corresponding to one active conductor, $N$ the active conductors per phase, and $2p$ the number of poles.

The coil-end *reactance ratio* (Par. 46) is—

$$q_{xf} = 1.48\, k_f \varphi_f \frac{k_2}{k_b k_p} \frac{\Delta}{\mathfrak{B}_1} \quad (18)$$

where $k_f$ ($= l_f/\tau$) is about 1.5 times the per cent. coil-pitch expressed as a fraction (somewhat larger for very high-voltage machines), and $k_2 = \tau/l$.

**50. Total leakage reactance.**

$$x = x_s + x_f = 2\pi f N 10^{-8}\left(k_p^2 l N_{ss} \varphi_s + \frac{N}{2p} l_f \varphi_f\right) \quad \text{(ohms)} \quad (19)$$

$$q_x = q x_s + q x_f = \frac{\Delta}{\mathfrak{B}_1}\left(4.44 \frac{\varphi_s}{N_{ss}} \frac{k_p}{k_b} + \frac{1.48\, k_f}{k_b k_p} \varphi_f k_2\right) \quad (20)$$

**51. Alternator vector diagram.** Assume a sinusoidal peripheral distribution of m.m.f. on both armature and field and a uniform peripheral reluctance. (This assumption is warranted in non-salient pole machines, but gives rise to considerable errors in some salient pole machines.) The resultant m.m.f. and gap-flux distribution will then also be sinusoidal.

Referring to Fig. 45, designate the flux by $\Phi$, the corresponding reluctance a.t. across gap by $R_1$, the armature amp-turns by $A_1$ (see Par. 44), and total a.t. across the gap by $F_1$ all sinusoidally distributed. These are all space vectors on the assumption that the field rotates counter-clockwise with respect to the armature, $R_1$ being the resultant of $F_1$ and $A_1$. In salient-pole machines substitute $F$ (the full field amp. turns $\times$ 1.27) for $F_1$ and the corresponding $R$ for $R_1$. This partly balances the error due to the unsymmetrical peripheral reluctance.

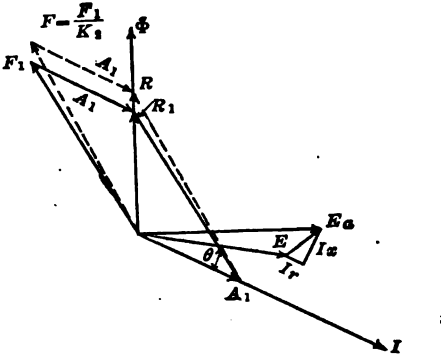

FIG. 45.—*General* alternator diagram for non-salient poles (full lines). Salient poles (broken lines).

Considering $\Phi$ as a time vector, the induced e.m.f. $E_a$ will lag 90 deg. Subtracting $Ir$ and $Ix$ from $E_a$ gives the terminal voltage $E$, where $\theta$ is the load phase angle. Hereinafter this diagram will be called the *general* alternator diagram.

**52. Application of alternator diagram to the regulation problem.** Given the winding data of armature and field, the armature resistance and leakage reactance, and the saturation curve, the excitation and regulation for any load and power-factor may be obtained as follows:

Digitized by Google

Starting with $E$ and $I$, add $Ir$ and $Ix$ to get $E_a$; from the saturation curve with full-load leakage (Figs. 41 and 46) take $R$; add $-A$ to get $F$, which is the required excitation. From the saturation curve corresponding to no-load leakage, take $E_F$; the regulation is then $(E_F - E)/E$. There are many variations of the above method, some of which are contained in Par. 56 to 58.

The rise of voltage when the load is thrown off is partly due to the release of the impedance voltage $Iz$, and partly due to the release of that part of the field m.m.f. employed in balancing the armature m.m.f., $A$. The first of these changes (*i.e.*, from $E$ to $E_a$) is dependent wholly upon the magnitude of $r$ and $x$ and the power-factor of the load, $r$ and $x$ being assumed constant. But the change from $E_a$ to $E_F$ is due not only to the magnitude and phase of $A$ but also to the degree of saturation of the magnetic circuit, *i.e.*, to the mean slope of the saturation curve between $E_F$ and $E_a$.

**53. Saturation factor.** The degree of saturation may be expressed in terms of the saturation factor, which is defined as the ratio of a small percentage increase in excitation to the corresponding percentage increase in the flux or induced voltage. The mean saturation factor between $E_a$ and $E_F$ is $\overline{ob}/\overline{ab}$ (Fig. 46). Designating this by $k_{sf}$, $E_F = E_a F/k_{sf} R$. The saturation factor should be taken from the saturation curve for no load leakage; but for other purposes, use the saturation curve for full load leakage. (See Par. 41).

**54. Short-circuit diagram and leakage reactance.** The short-circuit diagram is given in Fig. 47. From this the leakage reactance may be computed as follows: From $F$ subtract $A$ (computed from Eq. 6) to obtain $R$; look up corresponding $E_a$ on saturation curve; $z = E_a/I$ and $x = \sqrt{z^2 - r^2}$. In most cases it is sufficiently accurate to subtract $A$ from $F$ numerically, since they are nearly in phase, and to assume $x = z$. $x$ may be obtained in a similar manner from the zero power-factor saturation curve, Par. 56.

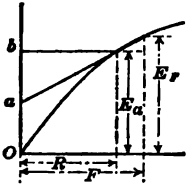

FIG. 46.—Defining saturation factor.

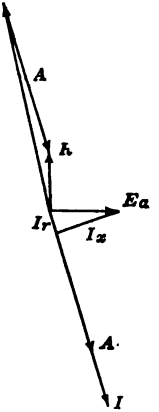

FIG. 47.—Short-circuit diagram for alternator.

In both of these cases however the results are very crude, since a small error in $A$ means a larger error in $x$.

**55. Load saturation curve for zero power-factor.** Referring to Fig. 48, curve $E_a$ is the no-load saturation curve with full-load field leakage, and $\overline{ob}$ is the field ampere-turns corresponding to a given armature current on short-circuit ($E = 0$). From Fig. 51, $\overline{ob}$ is approximately equal to $A'$. $\overline{ab}$ is laid off equal to $A$, the armature m.m.f. Then $\overline{oa}$ approximately equals $R$ (Figs. 47 and 51), and $\overline{ac}$ is approximately equal to $Ix$. If any load has zero power-factor and the same current as that assumed on short-circuit, $Ix$ will be approximately in phase with the terminal voltage $E$, and at right angles to $I$. Thus for any point $E_a$ on the no-load characteristic, the terminal zero power-factor voltage for the given current will be obtained by subtracting $Ix$ vertically, and adding $A$ horizontally. The zero power-

Digitized by Google

factor saturation curve will then be obtained by drawing lines from $E_o$ equal and parallel to $\overline{cb}$, as shown. The fact that $Ir$ is neglected is not significant, since it is in this case at right angles to $E$ and does not affect the result appreciably. This curve may also be determined experimentally.

**56. Load saturation curves at other power-factors.** If the load saturation curve at other power-factors could be obtained, it is obvious that the regulation and excitation for any power-factor and terminal voltage could be obtained directly therefrom. A semi-empirical method of obtaining these curves, recommended in the latest edition of the Standardization Rules of the A. I. E. E. is given in Sec. 24.

**57. E.m.f. method.** This method practically assumes a field flux wholly dependent on the field m.m.f., as given by the saturation curve, and that all the drop is due to an internal impedance which is commonly called the **synchronous impedance**, $z_s$, of which the **synchronous reactance** is $x_s$. Fig. 49 shows saturation and short-circuit characteristics with the derived synchronous impedance curve, the ordinates of the latter being the ratios of corresponding ordinates of the other two.

**58. The m.m.f. method.** This method is best understood by reference to Fig. 50, where the general diagram is dotted in. Starting with $E$ and $I$, add $Ir$ to $E$ to get $E'$, which is assumed to be the total induced e.m.f., corresponding to $R'$ as taken from the saturation curve. From $R'$ subtract the m.m.f. $A'$ taken from the short-circuit characteristic corresponding to the particular current in question. $A'$ is the $F$ of Figs. 47 and 51 and includes with the armature *m.m.f.* $A$, an additional *m.m.f.* $\overline{AA'}$ (Fig 50), which is practically equivalent to $R$ of Fig. 47, and which is the approximate m.m.f. equivalent of $Ix$. Under short-circuit conditions, $E' = Ir$ and the diagram reduces to Fig. 51, whence it is obvious that the field ampere-turns at short-circuit practically corresponds with what we have called $A'$.

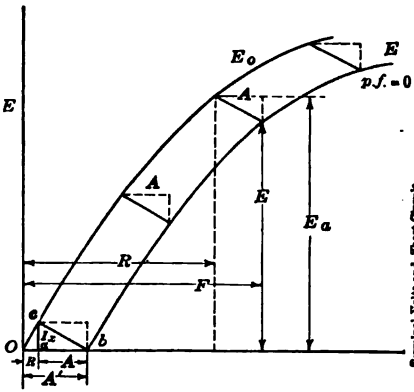

FIG. 48.—No-load saturation curve and zero-power-factor load saturation curve.

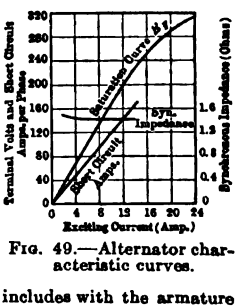

FIG. 49.—Alternator characteristic curves.

**59. Excitation characteristics.** Curves showing the relation of excitation (for constant terminal voltage) to the load current, at various power-factors, are shown in Fig. 52 for a 1,600 kv-a. slow-speed alternator with close regulation, and in Fig. 53 for a 6,250 kv-a. turbo-alternator with poor regulation. These were computed by the m.m.f. method.

**60. Relation of regulation to per cent. armature strength and length of air gap.** A study of Figs. 45 and 50 will show that for a given current and power-factor, the regulation depends upon the following ratios

$$Ir/E_o = q_r;\ Ix/E_o = q_x \text{(see Eq. 20)};\ \frac{A}{R} = q_A$$

Digitized by Google

and the saturation factor, $k_s$; and that except for their relation to the saturation, a given $q_s$ will have exactly the same effect as the same numerical

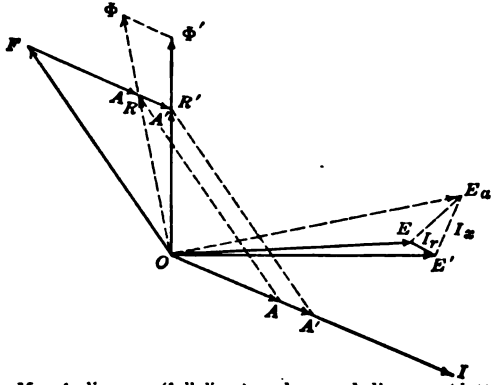

FIG. 50.—*M.m.f.* diagram (full lines) and *general* diagram (dotted lines).

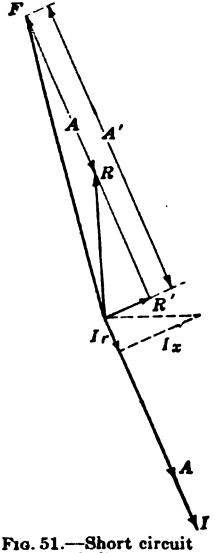

FIG. 51.—Short circuit m.m.f. diagram.

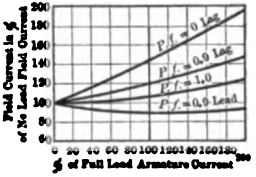

FIG. 52.—Excitation characteristic curves for a 1,600-kv-a. slow-speed alternator with relatively long air gap.

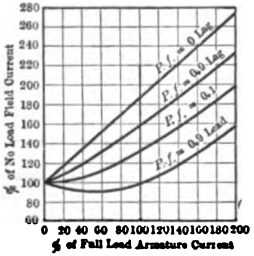

FIG. 53.—Excitation-characteristic curves for a 6,250-kv-a. turbo-alternator with relative short air gap.

$q_A$. In the m.m.f. method, $q_s$ and $q_A$ are combined in $q = A'/R'$ (see Fig. 50) and $q = q_A + q_s$ approximately, $= A' + R'$ approx.

Digitized by Google

Of these four ratios, $q_r$ varies from less than 0.005, in large turbo-alternators, to 0.02 or more in small slow-speed machines; $q_s$ from 0.04 to 0.15 or more; $q_A$ from 1.00 to 0.35; and $k_{sf}$ from 1.5 to 2.0. These last two are the dominant factors in regulation.

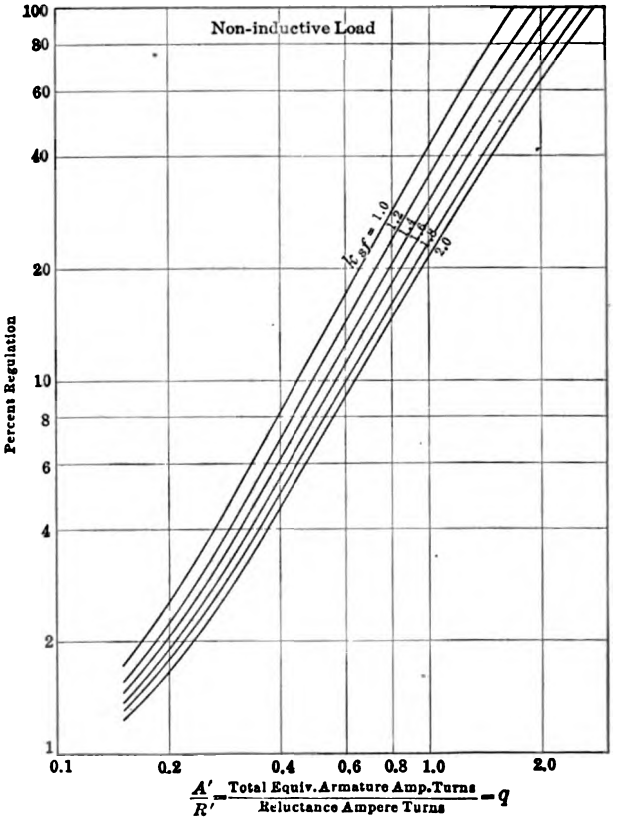

FIG. 54.—Per cent. regulation plotted in terms of per cent. armature reaction.

Since (approximately) $R = 0.313\mathfrak{B}_1\delta/(K_1K_dK_2)$ (see Par. **33** and **40**),

$$q_A = (A/R) = (1.43k_bk_pK_1K_dK_2\Delta\tau)/(\mathfrak{B}_1\delta) \qquad (21)$$

or taking average values for the $K$'s,

$$q_A = 0.9(\Delta\tau)/(\mathfrak{B}_1\delta) \qquad (22)$$

Digitized by Google

Thus assuming $\mathfrak{G}_1$ and $\Delta$ to be fixed for any given case, the regulation at a given power-factor is largely dependent upon the ratio of pole pitch to air gap and upon the saturation factor.

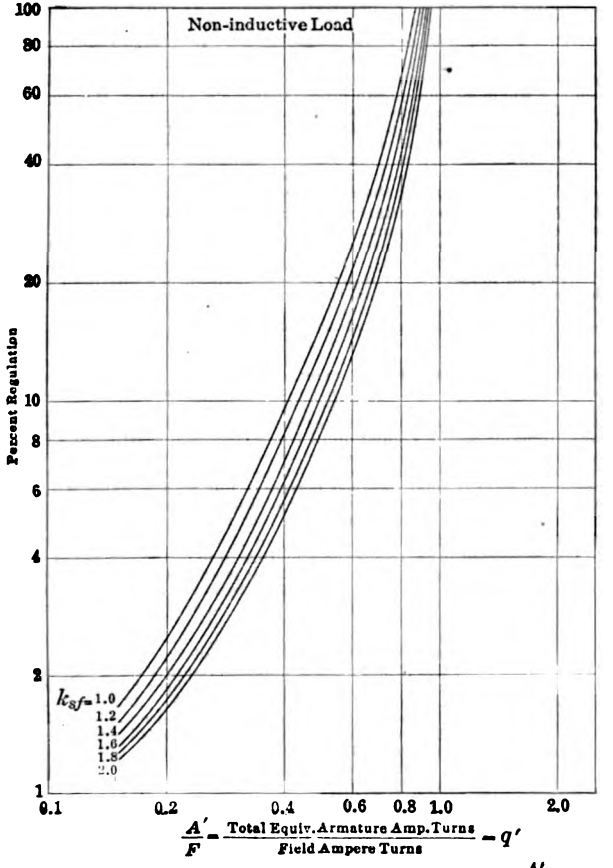

FIG. 55.—Per cent. regulation plotted as a function of $\frac{A'}{F}$.

From the Alternator Diagram (Fig. 45), with some approximations we get, for non-inductive load,

$$\text{Reg.} = \frac{1}{1-q_r}\left[\sqrt{1+q^2}\left(1-\frac{1}{k_{sf}}\right)+\frac{\sqrt{1+q^2}}{k_{sf}}\right]-1 \text{ (roughly approx.)} \quad (23)$$

Digitized by Google

Substituting average values for large machines, $q_r = 0.005$, $q_s = 0.07$.

$$\text{Reg.} = 1.005\left(0.007 + \frac{\sqrt{1+q^2}-1.0024}{k_{sf}}\right) \quad \text{(roughly appox.)} \qquad (24)$$

or in terms of $q' = A' + F$;

$$\text{Reg.} = 1.005\left(0.007 + \frac{1+\sqrt{1-q'^2}-1.0024}{k_{sf}}\right) \quad \text{(roughly approx.)} \qquad (25)$$

Figs. 54 and 55 are plotted from Eqs. 24 and 25. For small low-speed machines where $q_r$ and $q_s$ are larger than here assumed, the curves will lie a little higher at their lower ends.

Thus good regulation means large $R'$ and long air gap, longer in proportion to $\Delta$ and $\tau$, *i.e.*, very long for large high-speed machines such as turbo-alternators. In fact, to obtain a regulation of even 10 per cent. in large turbo-alternators would necessitate a tremendous air gap and more field copper than there is room for.

**61. Value of close regulation.** With automatic voltage regulators such as now employed, close regulation is no longer necessary even in small plants. Moreover large low-reactance machines are dangerous in case of sudden short-circuits (Par. 62 to 64). If, however, the ratio of armature ampere-turns to field ampere-turns is too high, the gap flux distortion in a salient-pole machine may be sufficient to seriously distort the e.m.f. wave. This does not apply with equal force to non-salient-pole machines, which include most of the large high-speed alternators, where large $q_A$ is commercially necessary.

**62. Short-circuits.** If the external impedance of an alternator be gradually reduced to zero, with full-load excitation and normal speed maintained, the short-circuit current, in terms of full-load current, will be $F/A' = 1 + q'$ (see Figs. 50 and 51), and correspondingly less at no-load excitation. If an alternator with a regulation of 5 per cent. and a saturation factor of 1.6, is short-circuited with full-load excitation, the short-circuit current will be about 3 times full-load current. At no-load excitation the short-circuit current will be 2.7 times full-load current. For an alternator with 20 per cent. regulation and a saturation factor of 1.6, the short-circuit current will be 1.56 for full-load excitation and 1.18 with no-load excitation.

**63. Sudden short-circuits.** Since on short-circuit, most of the field m.m.f. is consumed in balancing the armature m.m.f., the net m.m.f. and the flux are greatly reduced. If the short-circuit is applied suddenly, the sudden decrease in flux induces a large e.m.f. and current in the exciting winding, which tries to keep the flux from changing, and as the electromagnetic inertia and the time constant of the combined circuits are large, an appreciable time elapses before the field is destroyed. Meanwhile the opposng m.m.fs. of armature and field rise until nearly all the field flux is shunted across between field and armature. To do this requires an m.m.f. as many times greater than that at full-load, as the full-load field flux is greater than the total full-load leakage flux (field and armature). Thus if $r = 1.12$ at full-load zero p.f., and $q_s = 0.10$ (salient pole slow-speed machine), the r.m.s. armature amperes will rise temporarily to nearly 5 times its full-load value, and owing to the fact that one of the phase currents will be boosted up above its zero axis, because of the position of that phase at the instant of short-circuit, the maximum instantaneous current in one phase may be nearly double the maximum value of the above r.m.s. current.

In non-salient pole turbo-alternators $r$ may be as low as 1.04, $q_s$ as low as 0.04, the r.m.s. current nearly 12 times full load, and the instantaneous maximum more than 20 times normal. This means mechanical stresses on coil ends more than 400 times normal, which is more than they can readily be made to withstand.

**64. Current-limiting reactances.** As the total leakage ($r - 1 + q_s$), should not be less than 0.15, external reactances must in some cases be supplied to protect against sudden short-circuits. See Par. 140.

**65. Rating of alternators.** As the armature current, irrespective of power-factor, determines the armature copper loss, it is customary to rate alternators in kv-a. rather than in kw. In fact at low power-factors, and therefore at smaller values of delivered power, but with a given current and

Digitized by Google

terminal voltage; the flux, core-loss, field current and field copper loss are all larger than at unity power-factor. Therefore the safe output is less for a given temperature rise. It is thus necessary to specify the lowest power-factor at which an alternator is expected to operate, in order that enough excitation may be provided, and the corresponding field copper loss dissipated without excessive temperature rise. The maximum safe voltage rating is that which can be maintained at rated current and power-factor with the excitation voltage available, and without overheating the fields.

**66. Automatic voltage regulators, external to alternator.** The most successful of these is the Tirrill regulator or some modification thereof. In principle it is merely a voltage-operated relay which closes a low resistance by-pass around the shunt-field rheostat of the exciter when the voltage is too low, and opens it when the voltage is too high. This relay vibrates continuously, so that the exciter-field current does not change at each contact by any considerable amount, but assumes a pulsating intermediate value depending on the percentage of time the by-pass is closed. With a little care this regulator will maintain the voltage as nearly constant as is ordinarily desired in commercial power plants.

## SYNCHRONOUS MOTORS

**67. Structure.** The synchronous motor is simply a synchronous generator with its function reversed. In structure it is substantially identical with the synchronous generator.

**68. Diagrammatic representation.** Owing to its simplicity the e.m.f. method of diagrammatic representation will be employed here, in spite of its considerable inaccuracy. A single-phase machine or a single phase of a polyphase machine will be considered. The conclusions will obviously apply to the other phases if any.

**69. Theory of operation.** Consider a synchronous machine driven at such speed and at such excitation that its e.m.f. ($E_2$), in frequency and magnitude, is exactly the same as that ($E_1$) of the supply circuit, of which

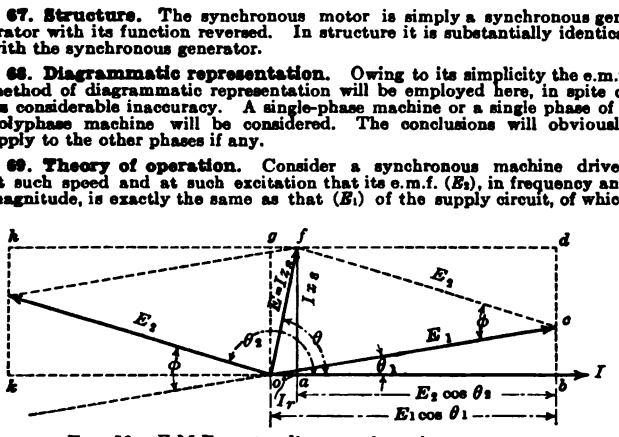

FIG. 56.—E.M.F. vector diagram of synchronous motor.

the voltage and frequency may be assumed constant. Assume also the phase of the machine voltage in exact opposition to that of the supply voltage. As these two exactly neutralize, there will be no current when the machine is connected to the supply circuit. Imagine now the driving power removed. The machine will begin to slow down; but as soon as the retardation begins, $E_2$ falls back (clockwise), yielding a resultant $E$, and a current $I = E/z_s$ (Fig. 56), where $z_s$ is the synchronous impedance of the motor. As $z_s$ is almost wholly synchronous reactance (the resistance being frequently not more than 5 per cent. of $x_s$), the current will lag almost 90 deg. behind $E$, and, for small values of $\varphi$, will be nearly in phase with $E_1$ and in opposition to $E_2$. Thus the power $P_1$ delivered by the supply circuit is $E_1 I \cos \theta_1$ (proportional to the area of the rectangle $\overline{obdq}$), the power $P_2$ transformed into mechanical form in the motor, is $E_2 I \cos \theta_2$ (proportional to the area of rectangle $\overline{abdf}$) and their difference $P_1 - P_2 = I^2 r$ is the armature copper loss in the motor (proportional to the area of the rectangle $\overline{oafq}$). Other losses are neglected.

Digitized by Google

The power ($P_2$) transformed is a function of $\varphi$, the coupling angle; it is

$$P_2 = \frac{E_2^2}{z_s}\cos\theta - \frac{E_1 E_2}{z_s}\cos(\theta - \varphi) \qquad \text{(watts)} \qquad (26)$$

The significance of the negative sign is that the electrical power is negative, *i.e.*, received rather than delivered. In Fig. 57, $-P_2$ is plotted against $\varphi$; whence it appears that as the motor lags (not in speed but in phase) behind the supply e.m.f., the output increases to a maximum, then decreases, becomes negative and returns to zero. As soon as $\varphi$ has opened out to a point such that $P_2$ is sufficient to carry the load, it will hang at that point as if the motor were driven by an elastic coupling. If the load increases, $\varphi$ will increase accordingly, until the maximum point is passed, when the motor will break down. During a little more than a half of each slip cycle (see Fig. 57), the motor is acting as a generator, since $-P_2$ is positive, and is in series short-circuit with the line. So much of the kinetic energy of momentum is lost during this half of the slip cycle that a synchronous motor will practically never pull back into step after once breaking, even if the mechanical load be immediately removed. For visualizing these relationships and their causes the Blondel diagram is by far the simplest device.

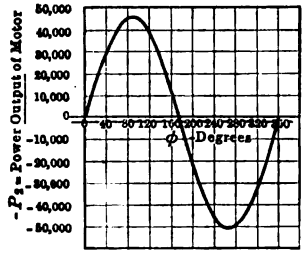

FIG. 57.—Synchronous motor output vs. coupling angle.

**70. Blondel diagram.** Referring to Fig. 58, the isosceles triangle $\overline{OAC}$ is constructed on the base $E_1$ with base angles, $\theta = \tan^{-1}(x_s/r)$. It can easily be shown that with constant impressed voltage $E_1$, and constant load,

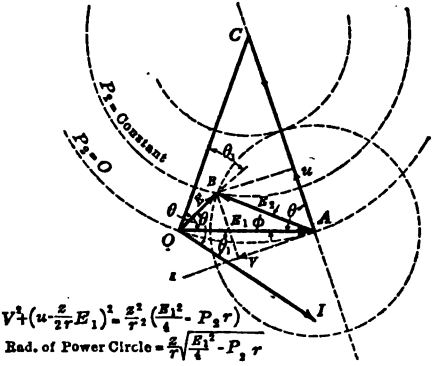

FIG. 58.—Blondel diagram for synchronous motor.

$P_2$, the locus of the point $B$, as the excitation and $E_2$ vary, is a circle with centre at $C$ and with radius $\sqrt{(E_1/2)^2 - P_2 r + \cos\theta}$. If $P_2 = O$, the radius is $(E_1 + 2\cos\theta) = \overline{CA}$, and the circle passes through $O$ and $A$. As $P_2$ increases, the radius decreases until it becomes zero, which corresponds to the maximum possible output with the given motor at the given impressed e.m.f. But this theoretical limit is never reached practically, because of the very large value of $E_2$ required to reach up to the high-power circles

Digitized by Google

of small radii. This will be better appreciated by reference to the diagram of Fig. 59, where the proportions are more normal and the point $C$ is far off the page.

For varying load and constant excitation, $B$ moves along a circle about $A$, clockwise for increasing and counter-clockwise for decreasing loads. The maximum load for any given excitation occurs when $B$ falls on $\overline{AC}$; beyond that $B$ swings around on to circles of smaller power, and the motor breaks down; *i.e.*, the decrease of $\cos\theta_2$ more than balances the increase in $I$.

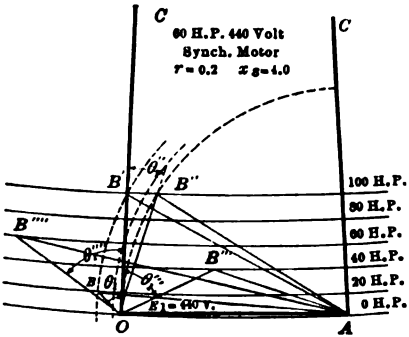

FIG. 59.—Portion of Blondel diagram drawn to scale.

**71. Interpretation of Blondel diagram.** In Fig. 58 the area inside of the zero-power circle corresponds to motor power, and that outside to generator power; the area to the left of $\overline{AC}$ corresponds to stable operation and that to the right to unstable operation; the area within the zero-power circle and between $\overline{AC}$ and $\overline{OC}$ corresponds to stable motor operation with a lagging current, and that to the left of $\overline{OC}$ to stable motor operation with leading current. The point $B$ is not only the extremity of the $E_2$ vector, but may be used also as the outer end of the current vector, since $E$ is proportional to $I$, and angle $\overline{COB} = \theta_1$. Thus when $B$ falls on $\overline{OC}$, $I$ is in phase with $E_1$ and $I$ is a minimum for that particular load. With normal steady load conditions, the angle $\phi$ never approaches the angle $\theta$, *i.e.*, the point $B$ never

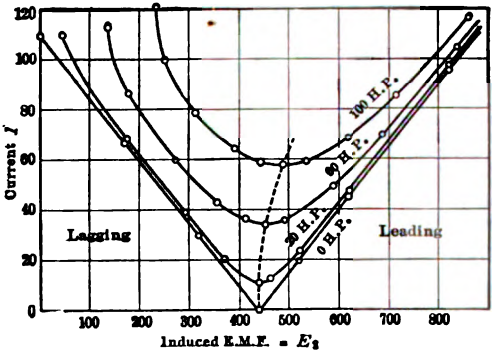

FIG. 60.—V-curves for 60-h.p. synchronous motor.

approaches the breakdown point on $\overline{AC}$ (see Fig. 59); but if either the load or the frequency of supply pulsates or changes suddenly, a hunting may be set up which will carry $B$ over into the region of unstable operation.

**72. Excitation and power-factor curves.** The familiar "$V$" curves of

Digitized by Google

current vs. excitation or induced e.m.f. may be easily obtained from the Blondel diagram. This has been done for a 60-h.p. motor, and the result is shown in Fig. 60. Power-factor curves similarly obtained, are shown in Fig. 61.

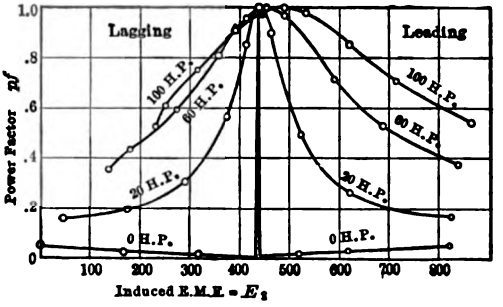

FIG. 61.—Power-factor curves for 60-h.p. synchronous motor.

**73. Synchronizing power.** By this is meant the stiffness of the coupling or the change in power absorbed per degree change of the coupling angle $\phi$, it increases with the air gap and inversely as $q'(=A'/F)$. See Par. **60.**

**74. Hunting of synchronous motors.** Owing to the elastic nature of the electromagnetic motor coupling, any impulse will tend to set up an oscillation about the position of equilibrium, which will continue until the energy by which it was initiated, is absorbed by the extra losses incident to the oscillation. Such oscillation is called hunting, and the absorption of the energy of oscillation is called damping.

**75. Hunting may be instigated** either by a temporary disturbance, such as a sudden change of load on the motor or of the frequency of supply, or by some periodic disturbance (Par. **76**) such as the pulsation of impressed frequency set up by the prime mover. This periodic disturbance may be one of comparatively high frequency due to the pulsation of the crank effort of a reciprocating steam or gas engine during each revolution, or one of comparatively low frequency due to the hunting of the governor of the prime mover.

**76. Frequency of hunting.** If the period of the impressed disturbance be approximately equal to that of the natural oscillation of the motor, there will obviously be a tendency for the motor to hunt with increasing amplitude, which may result in a complete breakdown or pulling out of step. A periodic pulsation in the load on the motor may also produce the same result, although such is much less common. It is thus important to know what is the natural frequency of oscillation of a synchronous motor, and upon what factors it depends.

The natural hunting frequency is approximately

$$f_h = 0.422\, E_1 \sqrt{\frac{pp'}{J z_s \text{ rev. per. min.}}} \qquad (27)$$

where $J$ is the moment of inertia in *lb. ft.*$^2$ and $p'$ the number of phases.

The $z_s$ used in Eq. 27 should be the combined impedence of alternator, line and motor. The smaller the motor as compared to line and alternator, the less will be the effect of line and alternator impedence upon the hunting period of the motor.

**77. Dampers.** Forced hunting may be considerably reduced and temporary oscillations more quickly damped out, by means of field dampers, consisting of : (a) a copper loop around each pole face; (b) a copper bridge between poles; or, better still, (c) a squirrel-cage set of copper conductors

Digitized by Google

through the pole face with end rings. These dampers tend to check pulsations of the pole-face flux due to the pulsating armature *m.m.f.*, by induced currents which absorb the energy of oscillation.

**78. Length of air-gap.** A short air-gap, other things being equal, results in a large synchronous impedance, a large per cent. armature reaction ($q_A = A + R$), a soft electromagnetic coupling, and a longer natural hunting period. This is desirable up to a certain point, as it decreases the frequency of hunting, improves the self-starting quality, increases the effectiveness of the damping devices and cheapens the machine; but there is an obvious limit to the desirable softness of coupling, namely, that beyond which there is danger of a motor breakdown. The value of $q'(=A'/F)$ should rarely be more than 0.6 when $F$ is taken at full-load and unity power-factor. Also, referring to the Blondel e.m.f. diagram, it appears that with a large $x_s$ (short air-gap) there will be a large variation in the power-factor of the motor from no-load to full-load under constant excitation, or a frequent adjustment of excitation will be demanded in order to maintain a constant power-factor.

**79. Self-starting synchronous motors.** The a.c. starting of the polyphase synchronous motor is as follows: If the field circuit of such a motor be opened and the armature be supplied with polyphase currents, there will result a fairly uniform field revolving around the periphery of the armature. Any energy transmitted across the gap to the field poles through the medium of this revolving field must be accompanied by a corresponding torque. Thus any hysteresis or eddy-current losses in the pole faces, due to the revolving field, represent a torque; or if the pole faces carry damping coils these will act as the short-circuited secondary of an induction motor, yielding a torque depending upon their reactance and resistance.

In this way a polyphase synchronous motor will supply a small starting torque, sufficient to start without load and run nearly up to synchronism; if it is a salient-pole machine it will then fall into step. Following this the field circuit of the motor may be closed and the motor is ready for the application of its load. If it is a non-salient pole machine, it will not come quite into synchronism until the field is excited, after which it will usually pull itself in step. It is sometimes even possible, with a little coaxing to start a polyphase motor when the only torque is that supplied by the hysteresis and eddy-current losses in laminated pole faces, although this is not a very satisfactory arrangement where frequent starting is required. With damping coils, however, a polyphase synchronous motor will start readily on reduced voltage and without excessive current.

**80. Polarity.** During acceleration with open-field circuit, the induced polarity in any given pole alternates less and less rapidly as the speed approaches synchronism. The final polarity of any pole, when the speed has reached synchronism, is largely a matter of chance and obviously may not be the same as produced by the field current as connected. If these polarities are in opposition, the revolving part will slip back one pole when the field circuit is closed, the large time constant of the field circuit allowing this to take place without serious shock. It is safer, however, to determine the polarity before closing the field circuit, and reverse the latter if necessary.

**81. Starting current.** As the chief function of the starting current is excitation, the shorter the gap the less the current required.

The minimum starting current for polyphase synchronous motors is usually such as to require only a portion of the line voltage for starting purposes, this being obtained by means of induction starters. If, for example, a certain motor requires in starting, double full-load current at half line voltage, the line current at starting would be practically equal to the full-load running current.

**82. Starting synchronous motors by external means.** Where the starting current is objectionable to the system, external means, such as d.c. or induction motors, must be employed. With single-phase synchronous motors, this is obviously necessary.

Chapter VI, of "Design of Polyphase Generators and Motors," by Hobart, sets forth reasons for employing synchronous motors more frequently. This reference contains descriptions of methods of building synchronous motors with high starting torques.

Digitized by Google

**83. Effect of differing impressed and induced wave shapes on power-factor.** When the impressed and induced e.m.f. waves are of different shape, the unbalanced e.m.f. harmonics produce wattless harmonic currents, which though small compared to the full-load current may be considerable with respect to the no-load fundamental current. Thus the p.f. at no-load may be less than unity even with the fundamentals of the current and e.m.f. in phase.

## SYNCHRONIZING

**84. Necessary conditions.** Impressed and induced e.m.fs. equal, opposite, and of same frequency.

**85. Synchronizing with lamps.** Connect lamps in series between the in-coming machine and the line. When the lamps are bright (or dark, according to whether the machines are connected in unison or in opposition in the synchronizing circuit), and the beats are very slow, showing opposition of phase and approximate synchronism, the line switch may be closed and the machine will quickly settle down to stable operating conditions. If a motor, the load may then be applied.

In the case of a three-phase machine, lamps should be connected in at least two phases, and if both sets are not dark at the same time, there is indication that the three phases are not connected in the proper order and that two of them should be interchanged. The chief objection to the use of lamps for synchronizing is that they do not tell just when the two e.m.fs. are in exact opposition, nor whether the in-coming machine is fast or slow, although with a little experience it is possible to become quite proficient in their use.

**86. Synchroscope.** Various electromagnetic instruments called synchronizers, synchronoscopes, synchroscopes, etc., have also been devised for indicating synchronism. In most of these, the principle of operation is that of the rotary field, synchronism being indicated by a pointer on a dial. When the in-coming machine is above or below synchronism, the pointer revolves in one direction or the other respectively, and at a rate proportional to the slip (or beat) frequency. At synchronism the pointer stands still, and in a position on the dial which indicates the relative phase of the two e.m.fs.

One form of synchroniser is constructed as follows: The armature consists of two coils at right angles connected in parallel, a non-inductive resistance in series with one and an inductive resistance in series with the other. The stationary field coil is connected to the supply bus and the armature to the in-coming machine. The split-phase revolving field produced by the armature currents, reacts on the alternating field to produce a rotation whose speed is equal to the difference between the frequencies of armature and field currents. When these are equal the armature coil remains stationary.

## PARALLEL OPERATION OF ALTERNATORS

**87. Mechanical analog.** When two or more alternators are connected in parallel and driven at the same frequency, they are as if coupled together by an elastic coupling just as in the case of a synchronous motor connected to a generator. Thus they must run at exactly the same frequency as long as they are coupled.

**88. Division of load.** Consider two similar alternators driven by separate prime movers, of which the speed characteristics are shown in Fig. 62, as $a$ and $b$. Then if the speed is that represented by the horizontal line $\overline{ss}$, the powers supplied by the two prime movers will be $P_a$ and $P_b$ respectively. The division of load will then be wholly dependent upon the speed characteristics of the prime movers, i.e., upon the governors.

**89. Division of reactive current.** The only effect of changing the excitation on either machine is to change the division of reactive current: *e.g.*, starting with equal loads and currents, if the excitation of $a$ be increased, it will take more of the lagging reactive current, and $b$ will take less. Any inequality of excitation is equalized by a circulating reactive current which transfers the excitation from the overexcited machine to the underexcited one. The terminal voltage will be determined in any case by the total excitation of both machines and by the magnitude and p.f. of the load.

When the voltage of a power plant is controlled by a Tirrill regulator, acting on the exciter bus from which the fields of all the parallel connected units are supplied, the per cent. increase in excitation for a given increase of load will obviously be the same on all the alternators. But if one alternator has a

Digitized by Google

close regulation and another poor regulation, and if in the first case they shared the active and reactive currents in proper proportion, with increased load the close regulation machine will be relatively overexcited and will take more than its share of the lagging reactive current.

**90. Switchboard control of speed of prime movers.** In prime movers with very close speed regulation (no-load to full-load), it is obviously necessary that the two speeds be very closely adjusted (Fig. 62), and this is often difficult by the cut-and-try method, which in some cases requires shutting down each time to adjust the governors. Large units are often provided with a means of governor adjustment during operation. This may be accomplished by means of a small motor connected through worm gearing to the governor adjustment and controlled from the switchboard.

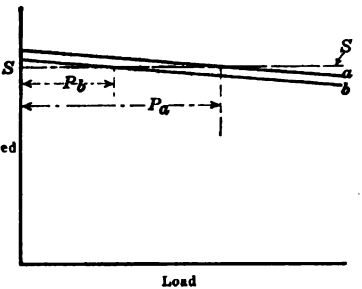

FIG. 62.—Diagram of division of load between two parallel-connected alternators.

**91. Governor damping to prevent hunting.** Sudden changes of load frequently cause the governor to hunt, *i.e.*, open up too wide, then close too far and so on. This may be easily prevented by a dash-pot connected to the governor.

## ELEMENTARY OUTLINE OF THE DESIGN OF SYNCHRONOUS MACHINES

**92. Specifications.** Every electrical machine is built to meet certain specifications whether proposed by the purchaser, his engineer, or the manufacturer. In addition to the customary specifications there is always the question of first cost which must be reduced to a minimum. Many of these specifications, requirements, or standards are thoroughly treated in the Standardization Rules of the American Institute of Electrical Engineers; these are given in Sec. 24. For a synchronous alternator the specifications refer briefly to the following: frequency; number of phases; rev. per min.; terminal voltage; rated output in kv-a.; minimum power-factor; temperature rise (Sec. 24); efficiency (Sec. 24); inherent regulation; per cent. leakage reactance volts; insulation tests (Sec. 24); wave form. These are not all specified in each case, whereas in some cases much more elaborate specifications dealing with the details of mechanical and electrical design are supplied. With reliable manufacturers, very simple specifications are ordinarily sufficient, telling chiefly what the machine shall accomplish rather than how it shall be built. In the case of many modern alternators, regulation is not a controlling specification, it being in most cases important to have a high reactance rather than a low one (Par. 63 and 64). Efficiency as such is also not directly a controlling factor in design, but chiefly as it is necessary to keep down the heat developed in the machine. A fraction of 1 per cent. in efficiency is not as important to the user as a safe operating temperature.

**93. List of symbols used.**

$\mathfrak{B}_1$ = Max. value of equivalent fundamental sine-wave of air-gap flux density (lines per sq. in.).
$\mathfrak{B}_g$ = Actual max. flux density in air-gap at pole-face (lines per sq. in.).
$\mathfrak{B}_{tr}$ = Maximum apparent tooth-density of flux (lines per sq. in.) in teeth.
$D$ = Diameter at air-gap (inches).
$d_s$ = Depth of slot (inches).
$e''$ = Volts induced per in. of active armature conductor.
$f$ = Frequency (cycles per sec.).
$h_s$ = Allowable copper watts per sq. in. of armature surface.
$K$ = kv-a. output.
$K_a$ = kv-a. developed in the armature.

Digitized by Google

$k_b$ = Belt differential factor.
$k_o$ = specific output.
$k_p$ = pitch differential factor.
$k_s$ = ratio of pole pitch to gross armature core length.
$l$ = gross armature core length.
$m$ = cir. mils per amp.
$p$ = no. of pairs of poles.
$q_A$ = ratio armature to gap amp-turns at full load.
$q_{il}$ = ratio of net iron length of armature to gross length.
$q_p$ = ratio of coil pitch to full pitch.
$q_{sw}$ = ratio of slot width to tooth pitch.
$R$ = rev. per min.
$T_c$ = Temp. difference in deg. cent. between armature conductor at centre and at end.
$v$ = peripheral velocity, ft. per sec.
$w'_c$ = wt. of armature copper (lb.) per kv-a. output.
$\Delta$ = peripheral loading; ampere conductors per in. of armature periphery.
$\xi$ = output coefficient.
$\tau$ = pole pitch (in.).

**94. Output equation.** The volt-amperes per sq. in. of peripheral surface (Par. **23** et seq.) are $\Delta e'' = 8.50 k_b k_p \Delta v B_1 10^{-8}$, and the total power developed, in kv-a. is, $K_a = 8.50 \pi k_b k_p \Delta v B_1 Dl 10^{-11}$. Allowing a maximum drop of 5 per cent. between induced and terminal volts, and taking $B_1$ corresponding to full-load, the kv-a. output is

$$K = 2.54 k_b k_p \Delta v B_1 Dl 10^{-10} = k_o Dl \qquad \text{(kv-a.)} \qquad (28)$$

or since $D = 720v \div (\pi R)$

$$l = 1.72 \times 10^7 KR \div (k_b k_p \Delta B_1 v^2) \qquad \text{(inches)} \qquad (29)$$

$k_o = 2.54 k_b k_p \Delta v B_1 10^{-10}$ is the **specific output**, or the kv-a. per sq. in. of projected area of the air-gap cylinder. By substituting for $v$ its value $\pi DR/720$, we obtain

$$K = 1.11 k_b k_p \Delta B_1 D^2 l R 10^{-12} = \xi D^2 l R \qquad \text{(kv-a.)} \qquad (30)$$

where $\xi = K/(D^2 l R) = 1.11 k_b k_p \Delta B_1 10^{-12}$ is called the **output coefficient.** Taking $k_b = 0.950$ and $k_p = 0.95$, this may be written, $\xi = (\Delta/1{,}000)(B_1/10^4)10^{-5}$. Sometimes $k_o$ and sometimes $\xi$ is more convenient as a starting-point for preliminary design, both being rough measures of the economy of material.

**Major design constants.** $B_1$, $v$ and $\Delta$ are the major design constants, since their choice ($R$ being specified) determines the general dimensions $D$ and $l$ of the machine. The larger these constants, the smaller in general will be the product $Dl$, and, within certain limits, the weight and cost of the machine. The considerations which govern the choice of these constants are so numerous that they cannot all be given their due weight in any direct method of attack. Some of the more important considerations and limitations are as follows: Par. **95** to **107**.

**Ratio of pole pitch to core length.**

$$k_s = \tau/l = 3.5 k_b k_p \Delta B_1 v^2 \div (10^7 f/KR)$$

**Number of poles.**

$$2p = 120f/R \qquad (31)$$

**Pole pitch.**

$$\tau = 6v/f \qquad \text{(inches)} \qquad (32)$$

**95. Tooth-density limit.** In order to avoid excessive eddy-current losses in the slot conductors and in the teeth, the flux density $B_{tr}$ at the narrowest part of the teeth should not exceed (for open slots) the values of Par. **42**, although for partly closed slots and stranded conductors 10 to 15 per cent. higher values are safe. $B_g$ is related to $B_{tr}$ as follows for the rotor or internal element, and parallel-sided slots:

$$\mathfrak{B}_g = \mathfrak{B}_{tr} q_{il} (1 - q_{sw} - 2d_s/D) \qquad (33)$$

and for the stator or external element

$$\mathfrak{B}_g = \mathfrak{B}_{tr} q_{il} (1 - q_{sw}) \qquad (34)$$

$\mathfrak{B}_g$ is usually slightly less than $\mathfrak{B}_1$, (the crest of the fundamental sine-wave of flux, see Fig. 23, and Par. **32**). Also in extreme cases the tooth saturation flattens the flux distribution curve still more. For laminations 0.014 in. thick, $q_{il}$ varies from 0.7, in an exceptionally well ducted core, to 0.8, in a poorly ducted core, and 0.9 in a core without ducts. Thus if $\mathfrak{B}_{tr}$ is assumed

Digitized by Google

at its reasonable upper limit, and $q_{al}$ is known, the relation of $\mathfrak{B}_g$ to $q_{av}$ is fixed.

**96. Heating limit.** At 60 deg. cent. the copper loss under 1 sq. in. of armature surface is $h_c = \Delta/m$, the resistance of one circ. mil. inch of copper at 60° cent. being just 1 ohm. $h_c$ is obviously limited: (a) by the heat dissipating power ($H_s$) per sq. in. per deg. cent. of temperature rise, (b) by the allowable temperature rise, $T$, (c) by the relative amount of core loss, and (d) by the relative amount of coil-end surface. Assuming average values of (b), (c) and (d), $H_s$ will vary with the nature of the ventilation, the peripheral velocity, and the amount of heat thrown off by the rotor. For open, salient-pole machines, a very rough preliminary guide is

$$h_c = \Delta/m = 0.4(1+0.016v) \quad \text{(watts per sq. in.)} \quad (34a)$$

For high-speed turbo-alternators $h_s$ has little relation to $v$, owing to the widely differing methods of ventilation, and varies from 0.8 to 1.6.

**97. Temperature gradient in slot conductors.** Assume that all the heat developed in the active conductor is conducted longitudinally to the coil ends. This is roughly true in high voltage stators. Then the temperature difference between centre and end of conductor will be $T_c = (l^2 \times 127^2)/m^2$, where $l$ is the gross core length in inches. Or if $T_c$ be limited, $l$ will be limited, thus $l = (m\sqrt{T_c})/127$. Thus the larger the value of $m$, the longer may be the armature core without excessive temperature differences. The table in Par. **98** gives the temperature differences in deg. cent. for various values of $l$ and $m$.

**98. Temperature differences between centre and end of armature conductors**

| $l$, Armature length (in.) | Temp. difference $T_c$ (deg. cent.) | | | |
|---|---|---|---|---|
| | 600 circ. mils per amp. | 800 circ. mils per amp. | 1,000 circ. mils per amp. | 1,200 circ. mils per amp. |
| 0 | 0.0 | 0.0 | 0.0 | 0.0 |
| 10 | 4.48 | 2.52 | 1.61 | 1.12 |
| 20 | 8.98 | 5.05 | 3.23 | 2.25 |
| 30 | 40.3 | 22.65 | 14.5 | 10.1 |
| 40 | 71.7 | 40.3 | 25.8 | 17.9 |
| 50 | 112.0 | 63.0 | 40.4 | 28.1 |
| 60 | 162.0 | 91.0 | 58.1 | 40.4 |
| 70 | 220.0 | 124.0 | 79.1 | 55.0 |
| 80 | 286.0 | 161.0 | 103.0 | 71.5 |
| 90 | 364.0 | 205.0 | 131.0 | 91.0 |
| 100 | 448.0 | 252.0 | 161.0 | 112.0 |

**99. Weight of copper vs. Δ.** With $h_c (= \Delta/m)$ limited, $m$ must increase with Δ. Then the total weight of active copper (also of total copper if $k_3$ be unchanged) will be proportional to Δ.

**100. Depth of slot.** On the same basis the slot depth will be proportional to $\Delta^2$. Slot reactance does not limit Δ and slot depth, as is sometimes the case with induction motors (see Par. **251**).

**101. Armature-reaction limit.** If on the score of regulation, e.m.f. wave shape, or stability, it be desired to keep $q_A (= A + R)$ within any given limit, it might become necessary to limit the ratio $\Delta/\mathfrak{B}$, see Eq. 22, Par. **60**.

**102. Choice of $\mathfrak{B}$ and Δ.** From the standpoint of the economy of material or of the maximum output coefficient, that value of $q_{av}$ is the best which results in the maximum product $\mathfrak{B}_1\Delta$. But since, for a given depth of slot, Δ increases as $\mathfrak{B}_1$ decreases, the maximum product will occur where the net width of slot (excluding insulation) is approximately equal to the minimum tooth width, *i.e.*, when $q_{av} > 0.5$. A considerable change in $q_{av}$ from the exact value which makes $\mathfrak{B}_1\Delta$ a maximum, does not seriously reduce this product, so that considerable variations from the best value of $q_{av}$ will be found, as there are other considerations involved.

$\mathfrak{B}$. Assume $q_{av}$ chosen, *e.g.*, to keep down the ratio $\Delta/\mathfrak{B}$ (Par. **101**), or to make $\mathfrak{B}_1\Delta$ a maximum (Par. **102**). Assume also $\mathfrak{B}_{tr}$ as chosen (Par. **95**); then $\mathfrak{B}_g$ is given by Eq. 34.

Δ. Assuming $h_s$ constant, the upper limit of Δ is likely to be set for turbo-alternators by the limited space for copper on the rotor, since this limits $F$, and $A$ (and therefore Δ) must be smaller than $F$. A glance at Fig. 63 shows that the cost of copper is not likely to set the Δ limit. In fact, an increase of Δ, within certain limits, results in a more than balancing saving in iron. Moreover, the correspondingly larger $m$ reduces $T_c$, the temperature difference between the centre and ends of the active conductors (see Par. **98**). If close regulation is specified, it may be necessary to use a low Δ and high $\mathfrak{G}_1$, see Par. **60**, particularly in high-speed turbo-alternators; but if, as is usually the case in this country at the present time, low regulation is not specified, Δ may be carried much higher than has heretofore been customary.

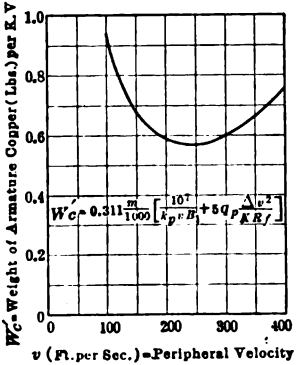

FIG. 63.—Armature copper per kv-a. vs. $v$, for a 10,000-kv-a. 25-cycle 2-pole turbo-alternator.

The following formulæ give a rough idea of the range of Δ for modern alternators: at 60 cycles $\Delta = (450 \text{ to } 700)(\text{kv-a.}/100)^{0.125}$; at 25 cycles $\Delta = (500 \text{ to } 800)(\text{kv-a.}/100)^{0.125}$. The higher values are for very well-ventilated and the lower for moderately ventilated machines (see Fig. 64).

**103. Choice of peripheral velocity.** Assuming that $\mathfrak{G}_1$ and Δ have been chosen, the choice of $v$ determines the proportions of the machine. Coil-end

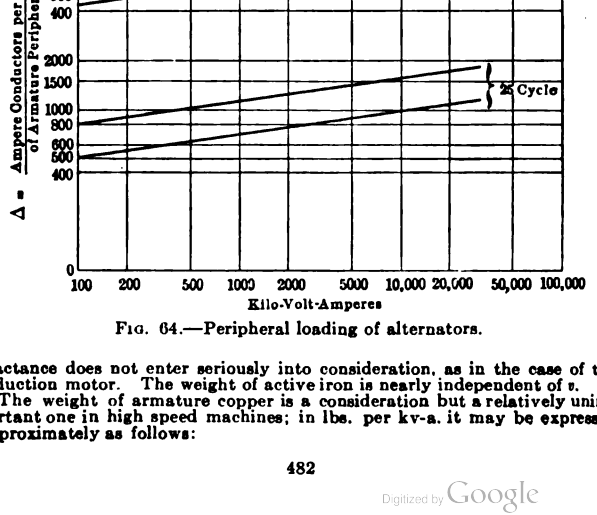

FIG. 64.—Peripheral loading of alternators.

reactance does not enter seriously into consideration, as in the case of the induction motor. The weight of active iron is nearly independent of $v$.

The weight of armature copper is a consideration but a relatively unimportant one in high speed machines; in lbs. per kv-a. it may be expressed approximately as follows:

Digitized by Google

$$W'_s = 0.311 \frac{m}{1{,}000}\left(\frac{10^7}{k_p v \mathfrak{B}_1} + \frac{1.5\times 10^7 q_s k_3}{k_p v \mathfrak{B}_1}\right)$$

$$= 0.311 \frac{m}{1{,}000}\left(\frac{10^7}{k_p v \mathfrak{B}_1} + 5\, q_s \frac{\Delta v^2}{KRf}\right) \quad \text{(lb. per kv-a.)} \quad (35)$$

which has its lowest value with respect to $v$ when

$$v = 100\sqrt[3]{\frac{KRf}{k_p q_s \Delta \mathfrak{B}_1}} \quad \text{and} \quad k_3 = \frac{1}{3q_s} \quad (36)$$

But for high speeds, this would result in a very long machine of small diameter and hard to ventilate; so that larger values of $k_3$ are usually employed for high speeds.

In Fig. 63, $W'_s$ is plotted against $v$ for a case where the following values obtain: $K = 10{,}000$; $f = 25$; $R = 1{,}500$; $\Delta = 1{,}200$; $\mathfrak{B}_1 = 40{,}000$; $q_s = 0.667$; $k_p = 0.866$; $m = 1{,}000$; from which it is obvious that $k_3$ may be increased considerably above the value corresponding to minimum copper, without considerable increase of cost. As $k_3$ varies proportionately with $v^2$, it is a critical ratio and useful as a guide to the determination of $v$, up to the mechanical limit. Rarely does $k_3$ occur outside of the range 0.6 to 1.4, being in general larger as the number of poles decreases, although each case must be considered by itself, and many other factors taken into account.

The *major considerations* affecting $v$ are those of ventilation and of mechanical design. A high $v$ means a diameter in direct proportion, a core length inversely as $v^2$, a much larger percentage of exposed coil-end surface, higher heat dissipating power and better ventilation, but a larger and more expensive frame and bearings. In large two-pole 60-cycle machines, the real upper limit of $v$ is that of mechanical strength. With solid cast-steel rotors $v$ may be carried as high as 420 ft. per sec.

**104. Machine proportions.** Having approximated $\mathfrak{B}_1$, $\Delta$ and $v$, the general dimensions of the machine are determined. Only some of the more important considerations have been possible here, but enough to give a crude notion of the more obvious factors.

**105. Caution.** The greatest care should be employed in making use of the values and limits here given for the various constants, as there are many other considerations and many details of design not here considered, which affect individual cases. Moreover, in commercial lines of machines, the necessity of utilising one punching or one frame for machines of several ratings, voltages, or speeds, results in kinks in the curves plotted from actual data.

**106. The air gap** in salient-pole alternators, when regulation is not important, may be reduced until the distortion of the flux across the pole face endangers the wave shape, or until pole-face losses become too large. On the first score $q_A$ (Par. 66) should not exceed 0.60, and on the second account the air gap should not be less than one-third of the slot opening in low-, and ½ in high-speed machines. In the case of non-salient pole high-speed turbo-alternators, one of the chief considerations governing the length of air gap is that of providing a sufficient path for the ventilating air (Par. 136).

**107. Effect of number of slots.** A small number of large slots means more heating of armature conductors, poorer wave shape, less insulation and lower cost.

## INSULATION

**108. Stator-slot insulation.** In the design of armature-slot insulations for high-voltage turbo-alternators, restrictions of a very serious nature are encountered. It is a comparatively simple matter to insulate 600-volt windings and provide liberal factors of safety, but when dealing with windings for 12,000 volts, it becomes necessary to employ very high-grade materials and to observe many important precautions in the manner in which these materials are applied. For a given material the disruptive strength per mil of thickness grows less as the thickness is increased. In this circumstance lies a serious handicap in designing the insulation for rotating apparatus wound for high pressure. For stationary apparatus which can be immersed in a tank of oil, reliance can be placed on the disruptive strength of the oil and of interposed barriers of insulating material, but in the insulation of armature windings, great regard must be paid to economy in space, and, furthermore, we cannot have recourse to immersion in oil.

Digitized by Google

On alternating-current machines of 1,000 volts and upward, the armature-slot insulating material may consist of micanite, micarta or Bakelised paper tubes, or of insulations built up of empire cloth, oiled linen, or other suitable materials. In Fig. 65 is given a curve showing suitable thicknesses of slot insulation from copper to iron in terms of the voltage.

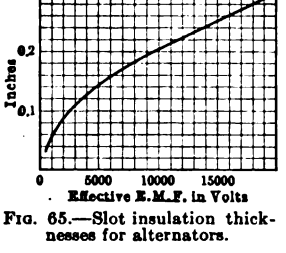

FIG. 65.—Slot insulation thicknesses for alternators.

**109. For heat-resisting qualities** and allowable working temperatures of different classes of insulations, see Sec. 24. Other references are as follows: A. P. Fleming and R. Johnson: "Chemical Action in the Windings of High-voltage Machines." *Journ.* I. E. E., Vol. XLVII, p. 530, 1911.

**110. Instance and cause of an insulation failure.** In 1905 Mr. J. S. Highfield published in *The Electrician* (Vol. LIV, p. 573) a description of an insulation failure in the windings of a 10,000-volt alternator. The failure was attributed to chemical actions stimulated by the ozone formed as a consequence of corona discharges. Highfield's article led to considerable correspondence in subsequent numbers of *The Electrician* and the views put forward are of great interest. "High-voltage Tests and Energy Losses in Insulating Materials," by Mr. E. H. Rayner appears on page 3, Vol. XLIX of *Journ.* I. E. E. (1912). Rayner concludes his paper with a large and valuable Bibliography of the subject.

**111. Effects of temperature on disruptive strength.** Lamme has dealt with these effects very thoroughly in his paper on "High-speed Turbo-alternators" appearing on page 1 of Vol. XXXII of *Trans.* A. I. E. E. (1913) Lamme and Steinmetz have continued the discussion of the subject in a paper entitled "Temperature and Electrical Insulation" which appears on page 79 of Vol. XXXII of *Trans.* A. I. E. E. (1913). As to the design of the insulation from the standpoint of the heat flow through it, the best information as yet available on the subject is contained in the following four papers: (a) Symons, H. D. and Walker M. "The Heat Paths in Electrical Machinery," *Journ.* I. E. E., 1912, Vol. XLVIII, page 674. (b) Williamson, R. B. "Notes on Internal Heating of Stator Coils," *Trans.* A. I. E. E., 1913, Vol. XXXII, page 153. (c) Langmuir, Irving. "Laws of Heat Transmission in Electrical Machinery," *Trans.* A. I. E. E., 1913, Vol. XXXII, page 301. (d) Randolph, C. P. "The Conduction of Heat; with Results of an Investigation of the Thermal Resistivity of Heat-insulating Materials," General Electric Review for Feb., 1913, page 120.

**112. Field insulation.** For the field windings of low-speed and moderate-speed synchronous machines the problems associated with the insulation are comparatively simple. Wherever reasonably practicable, the field winding will consist of a flat-ribbon conductor wound on its thin edge. It is important that the design shall comprise features ensuring absolute absence of any relative motion between the conductors, as the result of centrifugal forces and of vibration. The use of coils of flat strip with the edges left bare in the customary manner, is excellent from the standpoint of ability to rapidly dissipate heat to the surrounding air in virtue of the rapid motion of these coils through the air. Since the voltage is low and the temperature moderate, it is practicable to employ the simplest methods, so far as the insulation is concerned. But in the case of extra high-speed turbine generators the field windings must be embedded in slots in the surface of the cylindrical rotor, and the difficulties of providing a suitable design of insulation are very great. It is true that the voltage of the excitation is low, but the difficulty arises from the high temperature to which the insulation is subjected. The facilities for ventilation are necessarily exceedingly poor, and the space for the copper is so restricted that it is necessary to operate the field winding at high current densities. The result is that portions of the insulation in the slots of high-speed rotors are usually subjected to temperatures much above 100 deg. cent. and frequently temperatures approaching 150 deg. cent. are experienced at the very hottest spots of the rotor insulation in designs of the most difficult ratings. Consequently

Digitized by Google

mica must be the chief ingredient of the insulation, notwithstanding that the voltages are very low. The construction must present the utmost rigidity since the slightest displacement of any insulating material will suffice to unbalance the rotor. The case is ably presented by Lamme in a section entitled Rotor Insulation on p. 29 of his paper on "High-speed Turbo-alternators," in Vol. XXXII (1913) of the *Trans.* A. I. E. E.

**113. Insulation of alternator leads and connections.** Acute problems are not often encountered in the insulation of the leads and connections, since, on the one hand, machines are rarely built for pressures in excess of 15,000 volts, thus eliminating the questions arising in connection with the insulating of extra high-pressure leads; and, on the other hand, the voltages in large machines are rarely lower than 2,000, so that there do not arise any questions associated with the handling of very large currents. This latter statement should be conditioned by calling attention to the instantaneous current flowing on the occasion of sudden short-circuits. Such a current (Par. 63) may for an instant amount to from ten to twenty times the full-load current of the machine and is associated with the development of enormous mechanical forces. Consequently the problems of leads and connections reduce chiefly to the provision of elaborate mechanical support for all leads, conductors and cables from the armature windings to the switchboard. The end connections of the stator windings must be elaborately supported; many fine machines were wrecked before this was realised. The end connections are sometimes lashed by stout bands of cord to heavy rings which are supported by stepped brackets constituting extensions of the frame of the machine. It would be futile to here attempt to describe all of the various methods to which resort has been had in solving this difficulty. These have been described and illustrated in various papers among which may be mentioned the following:

Walker, Miles. "Short-circuiting of Large Electric Generators," *Journ.* I. E. E., 1910, Vol. XLV, p. 295.

Field, A. B. "Operating Characteristics of Large Turbo-generators," *Trans.* A. I. E. E., 1912, Vol. XXXI, p. 1645.

Lamme, B. G. "High-speed Turbo-alternators," *Trans.* A. I. E. E., Vol. XXXII, p. 1.

**114. Requisite protection against potential stresses caused by special conditions, grounded phase, switching, etc.** If a Y-connected generator is operated with the common connection grounded without any resistance, then if a dead short-circuit to ground occurs on one of the three lines, although the circuit-breakers will at once disclose the faulty line, severe mechanical stresses will be imposed on the windings of the generator, due to the sudden short-circuit. If on the other hand, the neutral point is connected to ground through a resistance, the amount of current which can flow when a dead ground occurs on one of the lines will be limited by the amount of the resistance. Let us consider the case of a Y-connected generator with a pressure of 7,000 volts in each leg of the Y, and with a 9-ohm resistance to ground. If a dead ground occurs on one of the lines leading from the generator, then asuming that the resistance of the winding and line and ground aggregate 1 ohm, only $7{,}000/(9+1) = 700$ amp. can flow through the ground. But this will raise the potential of the neutral point from zero to $700 \times 9 = 6{,}300$ volts, and this combined with the pressure of the other two phases, on which no ground has occurred, will increase the pressure between the high-tension ends of these windings and the frame of the machine to about 12,000 volts. Thus while the use of a resistance between neutral and ground *decreases* the severity of the mechanical stresses to which the windings of the generator will be exposed on the occasion of sudden short-circuits on the line, it *increases* the severity of the potential stresses on the main insulation.

The extra stresses imposed upon the main insulation of the machine would be still greater were the machine to be operated with its neutral grounded through a resistance, and with its terminals tapped into auto-transformers by means of which the generator voltage is stepped up (say in the ratio of 1 : 2) to the line pressure. Consequently when auto-transformers are employed, the generator must not have its neutral connected to ground through a resistance, but must be dead-ground. If the stepping-up is accomplished by means of transformers with distinct primaries and secondaries instead of with auto-transformers, then the generator's neutral may be grounded through a resistance. **Operation with grounded neutral** is to be pre-

Digitized by Google

ferred for systems from which many expensive underground cables are supplied, since a ground on some one cable will clear that cable off the line by the opening of its local circuit-breakers and without interruption to the rest of the system. But for a system consisting of a single long line with an important distribution system at its distant end, and where, consequently, any interruption of the supply would be very serious, there is a widely held opinion that the generator should be operated with non-grounded neutral, since it is maintained that the development of a ground at some one point of the line is then less likely to shut down the system. It will, however, increase, by 73 per cent., the extreme potential stresses across the generator's main insulation, and this must be recognized in the proportioning of the generator's insulation.

Switching operations, arcing grounds, lightning-arrester discharges, and other disturbances are likely to occasion surges in a system. The generator windings must be protected against the resulting high-potential stresses. Sometimes such protection is afforded by suitable reactances interposed between the line and the generator, and sometimes the last few turns in the winding are especially insulated so that the steep potential wave front shall not occasion breakdown between adjacent turns.

## LOSSES AND EFFICIENCY

**115. Core losses.** The data in the following table serves as an approximate guide to the determination of the *no-load* core loss in synchronous machines.

| Density in stator core (below slots) lines per sq. in. | Core loss in stator core (including teeth) (watts per lb.) | |
|---|---|---|
| | 25 Cycles | 60 Cycles |
| 40,000 | 1.1 | 2.7 |
| 50,000 | 1.4 | 3.7 |
| 60,000 | 1.7 | 4.9 |
| 70,000 | 2.0 | ..... |
| 80,000 | 2.4 | ..... |
| 90,000 | 2.8 | ..... |

There are further core losses called *stray* core losses which increase as the load increases. These are due to the flux distortion in core and teeth, caused by the armature m.m.f.

**116. Effect of rated speed on losses.** Returning to a consideration of the no-load core losses it is of interest to note that the inherent nature of low-speed and high-speed designs is such that while the no-load core loss may constitute a relatively small component of the total loss in low-speed synchronous machines, it is necessarily a large component in high-speed synchronous machines. The reverse is the case with the armature copper loss, which is relatively high in low-speed machines, and relatively low in high-speed machines. In a group of 3,000-kv-a. 25-cycle close-regulation designs for various speeds, particulars of which are given by Hobart and Ellis in "High-speed Dynamo Electric Machinery" (John Wiley and Sons, N. Y., 1908), the rated speeds and these two losses in per cent. of output are as follows:

| Rated speed | No. of poles | *A* No-load core loss (%) | *B* Armature copper loss at full-load (%) | Ratio of *A* to *B* |
|---|---|---|---|---|
| 83 | 36 | 1.93 | .93 | 2.07 |
| 125 | 24 | 2.02 | .73 | 2.77 |
| 250 | 12 | 2.17 | .57 | 3.82 |
| 375 | 8 | 2.24 | .50 | 4.45 |
| 500 | 6 | 2.27 | .50 | 4.39 |
| 750 | 4 | 2.30 | .47 | 4.92 |

Digitized by Google

**117. Armature copper losses.** In addition to the normal $I^2R$ loss, there are eddy current losses due to the flux fringing into the tops of the slots, depending largely upon the tooth density; and also eddy losses due to the cross slot leakage flux, depending largely upon the slot depth and the size of the conductor. Consequently each effective armature conductor is usually built up of many small component conductors in parallel. Since economy of space is of the utmost importance in the slots of extra high-speed alternators, each of these component conductors is usually of rectangular cross-section. The subject of subdividing conductors to eliminate eddy losses has been dealt with by A. B. Field in a classical paper "Eddy Currents in Large, Slot-wound Conductors," *Trans.* A. I. E. E., 1905, Vol. XXIV, p. 761.

**118. The field copper loss** is usually less than 1 per cent. of the output, and this percentage does not vary much with different ratings, since as the number of poles decreases, the length per turn and the ampere turns per pole increase. In non-salient pole machines this loss is relatively larger and is for designs of all speeds, a fairly considerable component of the total loss in a machine. For relatively low-speed machines this is partly due to the relatively large number of field spools among which the loss is distributed and each of which must provide a fairly large magnetomotive force. In extra high-speed machines, the considerable amount of field copper loss is, in part, a consequence of the high armature magnetomotive force per pole to be offset at low power-factors. In addition it can partly be traced to the deep air gap which must be provided in order that sufficient cooling air may be circulated through the machine. Finally, field copper loss in this type of machine is high, because of the limited space in the rotor slots, which renders it necessary to employ somewhat high current densities, in spite of the consequent high temperatures. Furthermore, in contrast to the salient pole machine, the field poles link with the flux at relatively low density, and some of them also link with only a part of the flux.

**119. Windage and bearing-friction losses.** When the air circulation is provided by fans integral with the rotor of a turbo-generator, the windage loss may be taken at about 3 watts per cu. ft. of air circulated per min., depending upon the efficiency of the fan employed and with the design of the passages in the machine through which the air is circulated. The quantity of air required for cooling extra high-speed synchronous machines ranges from 2 to 5 cu. ft. per min. per kv-a. (Par. 132). In large steam turbine-driven alternators, the total windage loss is usually a matter of about 1.5 per cent. of the output. Of this amount, about half represents the power required to drive the fan.

For moderate-speed and slow-speed machines not employing fans for ventilation, allowances ranging from 1.0 per cent. in small machines down to 0.5 per cent. in large machines are usually made for windage and bearing friction. A further consideration controlling the magnitude of the allowance relates to the number of bearings whose friction loss should fairly be charged to the generator as distinguished from the prime mover. Where, for testing purposes, the synchronous machine can be separated from the prime mover and driven by a small motor, the windage and bearing-friction loss may be determined by test when the machine is built.

**120. Actual windage and bearing-friction losses, for several large turbo-alternators**

| No. of poles | Rated output (kv-a.) | Speed (rev. per min.) | Circulating air (cu. ft. per min.) | Losses in kilowatts | | | | |
|---|---|---|---|---|---|---|---|---|
| | | | | Friction of bearings for the set | Do. for the generator alone | Windage of gen. excl. of fan | Do. of fan | Friction and windage of generator |
| 4 | 2,500 | 1,800 | 13,000 | 25 | 13 | 40 | 11 | 64 |

| 2 | 2,500 | 1,500 | 3 | 20 | 4 |

**122. Summary of losses.** We have now reviewed the component losses in synchronous machines. These are: (a) no-load core loss; (b) extra core loss increasing with load; (c) full-load copper loss in armature winding; (d) eddy loss at full-load in armature winding; (e) field copper loss at full-load; (f) windage and bearing friction loss.

Losses (a), (c), (e) and (f) may be considered accurately determinable either by test or calculation. Losses (b) and (d) are not commercially determinable; *i.e.*, their determination would require an elaborate and expensive investigation in each case. A reasonable value may be assigned to the sum of losses (b) and (d) (Par. **127**), in cases where they cannot be determined from tests. It may in general be stated that all the losses except loss (b) and loss (d) are readily susceptible to either exact or sufficiently approximate determination, and hence they may be designated as **determinable losses.** It is in commercial transactions futile to attempt to conclusively determine losses (b) and (d). Consequently it is desirable to group these two losses together, and to designate them as: **indeterminable losses or stray losses.** It should usually be practicable in a commercial transaction, involving efficiency guarantees, for the parties to the transaction to agree upon a reasonable value to assign in any case to the indeterminable losses in the event that it is not expedient to make the test set forth in Sec. 24.

**123. The efficiency.** The true efficiency of a machine is the ratio of the output to the input. The efficiency should be based upon the rated output, pressure, power-factor and speed. The losses on which the efficiency is based, should be corrected to 75 deg., the temperature of reference for efficiency determinations (see Sec. 24). The determination of the true efficiency of a machine involves either an accurate determination of all the component losses, or else an accurate measurement of the output and of the simultaneous input. In other than small machines, both of these methods of determination are impracticable unless resort is made to expensive scientific measurements.

Consequently in practice, use should be made of two approximate efficiencies. These may be designated as follows: (a) the efficiency exclusive of stray losses; (b) the conventional efficiency.

**124. The efficiency exclusive of stray losses.** This is the ratio of the output of the machine to the sum of the output and the determinable losses as obtained by the separate measurement or calculation of each determinable loss. This efficiency is necessarily greater than the true efficiency, but approaches it in machines in which the indeterminable losses are negligible.

**125. The conventional efficiency** differs from the efficiency exclusive of stray losses, to the extent to which appropriate values for the indeterminable losses are included in estimating the input. In all matters relating to guarantees, the allowances to be made for the indeterminable losses are specified in each case. The conventional efficiency is, by definition, less than the efficiency exclusive of stray losses, except in cases where the convention is to take the stray losses equal to zero (see Standardization Rules, Sec. 24). With the application of a reasonable amount of care in assigning appropriate values to the indeterminable losses, the difference between the conventional efficiency and the true efficiency should usually be quite unimportant and often negligible.

Digitized by Google

**126. Stray losses.** A realisation of the extensive nature of the stray losses has only gradually taken place. It is by no means unusual for the stray losses to amount to from 25 to 50 per cent. of the no-load core loss. These stray losses arise from various causes; a notable cause exists in the local variations in the reluctances of the magnetic circuits around the individual slots and groups of slots with the continually varying relative positions of stator and rotor. Although such losses are not a function of the no-load core loss, nevertheless practical purposes are sometimes fairly served by assuming the stray losses to be equal to half of the no-load core loss. For example, in a certain machine with a rated output of 2,000 kw. we may have the following losses: armature copper loss, 10,000 watts; field copper loss, 20,000 watts; core loss at no-load, 12,000 watts; bearing friction and windage, 15,000 watts.

With this assumption as to the stray loss, the total of all losses at full-load amounts to $10,000+20,000+12,000+15,000+6,000=63,000$ watts. The full-load efficiency will then be taken as: $2,000,000/(2,000,000+63,000)=96.9$ per cent.

**127. Determination of stray losses.** An approximation to the stray losses may be obtained by operating the machine at its normal speed and with sufficient excitation to circulate rated current. From the power required to operate the machine thus, the friction loss and the copper loss should be subtracted, and the remainder taken as the stray loss at full-load. Experience indicates that in many cases this is a fair approximation. If it were true, then in order to drive the above-mentioned 2,000-kw. machine at normal speed and with full-load current circulating in the short-circuited windings, it would be necessary (if the stray loss at full-load amounted to 6,000 watts), to supply to it (exclusive of field excitation), $10,000+15,000+6,000=31,000$ watts. (See Sec. 24.)

**128. Variation of stray losses with load.** The nature of the stray losses is too vague to justify any positive statement as to the laws of its variation with the load. It may in some instances vary as the square of the load. But with a view to practical liberality it is well to determine upon a representative figure for its full-load value and arrive at figures for its value at other loads by assuming it *directly* proportional to the load.

## VENTILATION

**129. The process of cooling and ventilating low-speed and medium-speed synchronous machines** is not one presenting any grave difficulties, since such machines are so large as to expose extensive surfaces to the surrounding air. In such machines the field coils are usually arranged on the salient poles of the revolving field. The fan action occasioned by the revolution of such a salient-pole field, may be readily supplemented by the provision of fan blades suitably disposed on the rotating structure. The fan friction is one component of the losses in the machine, and serves to decrease the machine's efficiency, particularly at light loads. The power required to drive the fans of such machines is comparatively small since the pressure developed by the fans is low.

**130. Stator ventilation.** Owing to the rapid flow of heat by conduction from the copper in the slot to the end connections, it is not always necessary to provide vertical ventilating ducts in the laminated core of a narrow machine provided it is arranged to cool the end connections vigorously. When this principle is employed, it is practicable, in reasonably narrow machines, to maintain the armature windings at a low temperature without resorting to the relatively expensive method of providing vertical ventilating ducts. In many high-voltage machines the thickness of slot insulation is such that most of this heat must flow to the coil ends, even with comparatively long coils, Par. 97-98.

**131. Rotor ventilation affecting diameter.** From the standpoint of rotor ventilation, a large diameter and a short core-length are desirable and permit of economy in field copper. But the gain, as regards decreased outlay for copper and magnetic iron when a large diameter is employed, may involve a very disproportionate increase in the outlay for frame and for bearing supports and for structural material in general.

With vertical-shaft machines it becomes practicable to resort to larger diameters than with horizontal-shaft machines, since in the latter type a short machine of large diameter requires a lavish outlay for material in order

Digitized by Google

to render the stator frame sufficiently stiff to ensure absence of sagging. Any sagging would unbalance the air gap, which must be of uniform depth over the entire circumference.

The field winding should usually consist of flat copper, wound on its thin edge. The heat then readily flows to the outer surface, and is carried away by the surrounding air.

**132. Intense forced cooling and ventilation.** Extra high-speed steam turbine-driven generators of large capacity present the most extreme instances of the necessity for forced cooling and ventilation. The quantity of air which must be forced through such machines per kv-a. of rated output in order to limit the temperature rise at full-load to permissible values, is of the order of from 2.5 cu. ft. per min. for a 25,000-kv-a. machine to 4.5 cu. ft. per min. for a 5,000-kv-a. machine, depending on the efficiency of the machine. The precise values vary with the arrangement of the ventilating passages, and the speed. The customary method of circulating the air consists in providing the rotor with fans which force air through appropriate passages. Fig. 66* relates to the ventilating method employed in the design

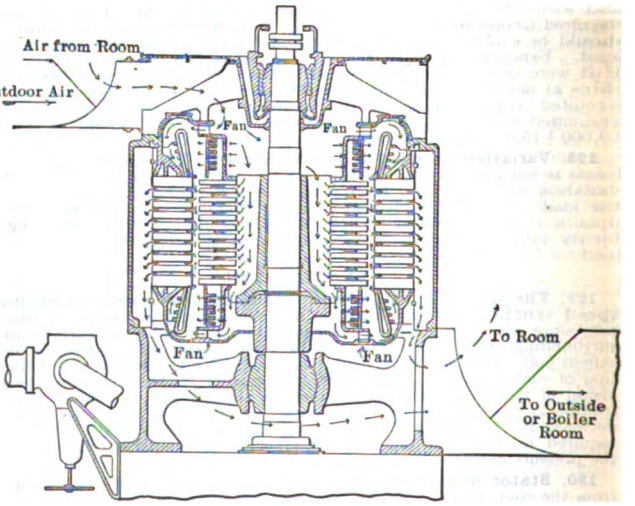

FIG. 66.—Ventilation design for a vertical-shaft turbo-alternator.

of a steam turbine-driven alternator of the vertical type. Mr. B. G. Lamme has dealt very fully with this subject in a paper entitled "High-Speed Turbo-alternators," at p. 1 of Vol. XXXII (1913) of the *Trans.* A. I. E. E. Lamme subdivides methods of cooling turbo-alternators by the forced circulation of air into three classes: (a) radial methods, (b) circumferential methods, and (c) axial methods.

**133. In the radial system of ventilation** all the air passes out radially through ventilating ducts in the stator core. In the design of these high-speed generators the rotor diameter is limited by the peripheral speed. Consequently the design is of relatively great length parallel to the shaft. There is very little space on the rotor even for the windings, owing to the limited radial dimensions, and it is often necessary to dispense with the circulation of

* From an article by E. Knowlton, "Ventilation of Steam Turbine-driven Alternators," *General Electric Review*, Oct., 1912, page 656.

Digitized by Google

air through the interior of the rotor. Even in the most favorable cases, such circulation of air through the rotor is limited to but a small part of the air required for the cooling of the stator. The greater part of the supply required for the stator is, in the radial system, first passed along the air gap; the radial depth of the air gap is often made very great expressly out of consideration for providing sufficient section for the flow of the required amount of air.

**134. A typical arrangement of the radial system** as applied by the General Electric Co. in its horisontal steam-turbine alternators is shown in Fig. 67. The system is described as follows: the air enters the generator at *AA*; passes through the air gap, windings and air ducts in the stator core to the annular spaces *BBB*; flows around circumferentially to the openings *CCC* in the bottom of the armature frame and thence to the outlet duct. In some machines part of the air passes through the field core. The movement of air is produced by fans on the ends of the rotor. In some instances the armature frame is modified so that the air is expelled from the top into the dynamo room. Proper passages must be provided below the generator for the ingoing and outgoing air. As shown in the sketch, air is taken in at both ends of the generator and discharged through an opening in the centre of the frame, and the passages must be so arranged as to prevent the outgoing heated air from mixing with the incoming cool air; a simple method of accomplishing this is also shown. In certain cases other arrangements may better suit local conditions. For approximation the area of the ingoing or outgoing duct will range from 5 sq. ft. for a 1,000-kv-a. to 15 sq. ft. for a 5,000-kv-a. generator. The outgoing air should be carried outside the building, care being taken that it cannot immediately re-enter the intake. The ducts should be as short and have as few bends as possible and these should be made with a large radius. Both ducts should have adjustable dampers so that part of the air may be taken from or expelled into the engine room. This will allow adjustments to suit weather conditions. The armature and field leads are brought out from the bottom of the generator frame, directly under the collector; this brings them to the air chamber under the armature. From here to the switchboard the leads may be carried in one of the air ducts or a separate duct, as is most convenient.

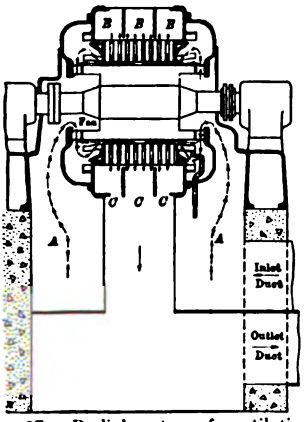

FIG. 67.—Radial system of ventilating a horisontal-shaft high-speed generator.

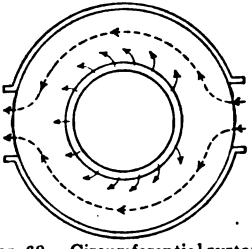

FIG. 68.—Circumferential system of ventilating turbo-alternators.

**135. The circumferential system of ventilation** is explained by reference to Fig. 68 (Lamme). The air enters at one side of the machine and is forced along the air ducts in the stator core back of the armature windings until it reaches the other side of the machine, whence it is discharged. Such circumferential circulation is usually supplemented by the supply of a further amount of air to the air gap to cool the rotor, as shown

Digitized by Google

by the 13 little arrows curved toward the centre of the diagram. This air, after leaving the air gap passes into the stator ventilating ducts and reinforces the main streams of air. Lamme also illustrates in his paper (Ref. in Par. 132) a modification of the circumferential system in which the air enters the stator ducts at points of their outer circumference, flows down alternate vertical ventilating ducts in the stator core, then a short distance through longitudinal ducts, and returns through the intermediate vertical ventilating ducts back to the outer circumference of the stator.

**136. The axial system of ventilation** (often termed the longitudinal system) is illustrated in Fig. 69 (Lamme). The system has the advantage that the edges of each lamination are bathed by the circulated air. The conduction of heat is many times greater in the plane of the laminations than transversely thereto, the ratio varying from 20 to 100 according to the nature of the insulation between laminations, the thickness of the laminations, insulation, and their compression. Obviously the longitudinal method has a decided advantage in this respect at least. On the other hand it is difficult to arrange that a sufficient extent of surface shall be exposed to the air. As shown in Fig. 69, there is provided in the axial system a large number of longitudinal passages. These passages may lead to a large central outlet duct as in the case illustrated, or they may extend uninterruptedly right through the core from one end to the other.

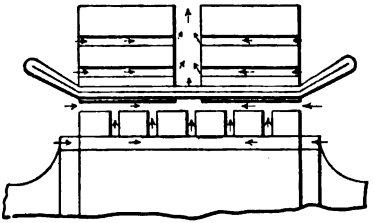

FIG. 69.—The axial system of ventilating turbo-alternators.

**137. Air cleaning and cooling.** It has been quite usual to take the ventilating air from the hot engine room, circulate it through the machine, and then return it to the hot engine room. Not only does this result in a high operating temperature (or else a lower output for a given temperature), but it also has the consequence that the air which is sent into the machine has taken up oily vapors whose presence aggravates the difficulties associated with the gradual clogging up of the ventilating passages in the machine with dust and dirt which is also carried into the machine in the circulating air. An expensive periodical cleaning of the machine must be undertaken.

In several important modern stations it is arranged that the air shall be taken from outside the station or from a cool basement (when one of sufficient capacity can be provided) cleaned by passage through cloth screens, and then led to the machine through suitable ducts. The cloth employed is of a closely woven variety similar to that known as Canton flannel, and there is required a surface of some two-tenths of a square foot per cu. ft. of air per min. Since a 10,000-kv-a. machine requires some 34,000 cu. ft. of air per min., it follows that for a machine of this capacity: $34{,}000 \times 0.20 = 6{,}800$ sq. ft. of screening surface must be provided. The cloth is supported upon wooden frames and the installation is generally regarded as constituting an undesirable risk from the insurance standpoint. Of the various kinds of cloth to which the term "fire-proof" is applied, it is rare to find any approach to genuinely fire-proof properties.

These air-filtering screens occupy a great deal of space and their effectiveness is gradually reduced as the meshes become clogged up with dust.

**138. Air washing.** Decidedly the best method of cleaning the air consists in passing it through sprays of water to wash it, instead of straining it through cloth screens. Mr. E. Knowlton deals at length with this method in the course of an article entitled "Ventilation of Steam-turbine Engine Rooms;" General Electric Review; September, 1913, page 627. See also a paper by J. Christie, entitled "Air Filtration, Cooling and Ventilation of Electrical Machinery;" Electrical Review; June 27, 1913, page 1088. Mr. Christie states that filter cloths wear out quickly and are expensive to renew. He states that $400 to $500 per annum for cloth and labor is by no means an outside figure for the efficient maintenance of this equipment.

Digitized by Google

**139. The cooling of air incident to water filtering.** The humidification of air in its passage through the water filter occasions a lowering of its temperature, the amount of which varies with the condition of the air. If it is utterly dry on entering the humidifier, the air will have experienced a considerable decrease in temperature by the time it has emerged from the humidifier and entered the machine which is to be cooled. As a consequence of these considerations, it is obvious that the average conditions regarding humidity and temperature in any locality, affect the amount of advantage to be derived by air filtering in addition to that of removing the dirt and the dust. The average reduction in the temperature of the air for the months of July and August in different parts of the United States is stated (Knowlton) to vary from 2.5 deg. cent. at points on the coast to 11 deg. cent. at points in the Middle South West. On certain days during these months the maximum reduction effected may considerably exceed these average values.

## MECHANICAL CONSTRUCTION

**140. Abnormal conditions requiring large factors of safety.** In providing adequate strength in the design of synchronous machines it is usually utterly insufficient to take the conditions in the machine when running at uniform speed at its normal load as the basis which, with usual factors of safety, will lead to a satisfactory design. On the contrary, it is the conditions occurring during sudden short circuits (see Par. 63 and 64), and when the machine is carrying sharply fluctuating loads, which determine the strength required in the various parts. These are impossible of exact calculation; consequently, in the design of all those parts upon which the mechanical strength of the whole machine depends, large margins of the nature of safety factors must be added to the values which would usually be employed in machine design.

**141. Critical speed of shafts.** Irrespective of questions of cost, conditions arise with some capacities and speeds where it is impossible to find room for a shaft of large diameter, and it must have a critical speed below the operating speed. The peripheral speed at the bearing would otherwise exceed desirable values; furthermore, there is but limited room for accommodating the windings in the radial depth available between the surface of the rotor (which is itself of small diameter) and the surface of the shaft.

**142. Effect of critical speed on rotor design.** If the critical speed is to be well above the normal running speed, it is impracticable to employ laminated rotor bodies for capacities much above 1,000 kv-a. at a speed of 3,600 rev. per min. or above 5,000 kv-a. at 1,800 rev. per min. or above 7,500 kv-a. at 1,500 rev. per min. But for designs in which the critical speed is below the normal speed, it is practicable to employ rotor constructions with laminated cores up to ratings of over 2,000 kv-a. at a speed of 3,600 rev. per min. of some 10,000 kv-a. at a speed of 1,800 rev. per min., and of some 15,000 kv-a. at a speed of 1,500 rev. per min. In the construction of 1,500 rev. per min., 25-cycle, or 3,600 rev. per min., 60-cycle rotors solid cores are especially appropriate, since greater mechanical strength can be obtained in constructions in which the slots for the windings are milled out of a solid steel core. The rotor windings may be retained in the slots by solid steel or brass wedges, since the magnetism is of constant direction in each part and since the air gap is so deep in these extra high-speed generators that there is no loss in the rotor surface from pulsating influences from the alternating m.m.fs. due to the conductors in the stator slots. In some designs the shaft ends consist of enlarged extensions bolted to the rotor core.

**143. Bearing lubrication.** In small and medium sized machines of moderate speed, the lubrication of the bearings is accomplished in the usual manner by oil rings located in suitable recesses in the bearing and with their lower portions immersed in oil below the bearing lining. In large extra high-speed machines, the oil is forced into the bearings and after passing from them and being allowed opportunity to cool, it is again forced into the bearings. Sometimes in such machines and frequently in large water-wheel generators, copper tubes are embedded in the bearing just under the surface of the lining metal. Water is circulated through these tubes and plays a large part in maintaining the temperature of the bearing at a safe value. The following description relates to the water-cooled bearings of some horizontal turbo-generators built by the General Electric Company.

Digitized by Google

The general construction, including the arrangement of the cooling pipe and the grooving, is shown in Fig. 70. The bearing is provided with a coil

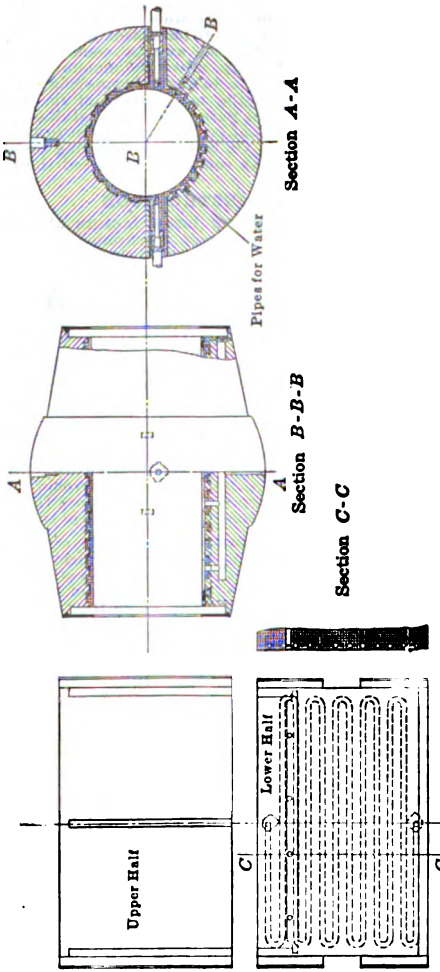

FIG. 70.—Water-cooled bearing.

of thin copper tubing cast into the babbitt lining close to the surface and having at the ends of the tubing, steel blocks securely brazed to the tubing and held in place by the babbitt. Water is led into the bearing by pipes

Digitized by Google

passing through stuffing boxes in the bearing standard. These pipes must be removed before taking out a bearing shell. In this way the heat of the bearing is taken up at the point where it is generated and there is no cooling coil needed in oil tank or in pipes.

In the case of vertical shaft machines the step bearing is maintained in condition by forced circulation of oil.

It is important in the design of the bearings for electrical machinery that no oil shall be thrown or leak out from the bearings, as it is liable to occasion harm to the insulation. Even though there may not be any apparent escape of oil, it may be present as a fine vapor and be thus taken up by the air in the engine room.

**144. Bearing pedestal.** It is only in small machines that the bearing pedestal continues to be a distinct and readily recognisable component. There is a tendency in modern machines to embody the functions of the pedestal either in the base or in the end shields.

**145. Frame.** In the case of the frames of low-speed alternators of very great diameter and small width, the design should be liberally stiffened with deep ribs. Any weakness in the frame of such a machine is certain to occasion trouble. In Fig. 71 is shown a liberal, box-type construction employed by the Westinghouse Co. in the design of a 5,000-kw. alternator. The internal diameter of this armature is 9.76 meters.

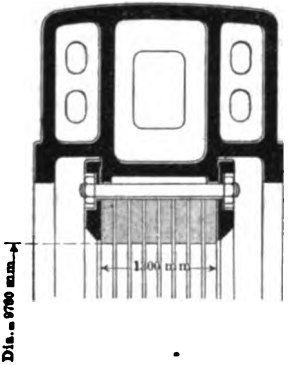

FIG. 71.—Box-type frame for 5,000-kw. alternator.

**146. Representative weights of turbo-alternators**

| Frequency (cycles per sec.) | Rated output (kv-a.) | Speed, rev. per min. | Weight of generator without base or bearings (lb.) | Weight of turbine including base and bearings but exclusive of accessories (lb.) | Weight of set (lb.) |
|---|---|---|---|---|---|
| 60 | 2,500 | 1,800 | 34,600 | 76,000 | 110,600 |
| 60 | 2,500 | 3,600 | 33,000 | 36,000 | 69,000 |
| 60 | 5,000 | 1,800 | 53,570 | 93,000 | 146,570 |
| 60 | 12,500 | 1,800 | 133,500 | 256,000 | 389,500 |
| 60 | 25,000 | 1,200 | 300,000 | 510,000 | 810,000 |
| 25 | 2,500 | 1,500 | 49,000 | 73,600 | 122,600 |
| 25 | 5,000 | 1,500 | 96,900 | 120,500 | 216,400 |
| 25 | 12,500 | 1,500 | 180,300 | 277,000 | 457,300 |
| 25 | 25,000 | 1,500 | 340,000 | 452,000 | 792,000 |

## THE TESTING OF ALTERNATING-CURRENT GENERATORS

**148. The heating test of large alternators** under normal full-load conditions is troublesome and expensive, even when the necessary amount of power is available, and many suggestions, such as those of Mordey and of Behrend,* have been made with a view to reduce the amount of energy wasted during the tests. These methods necessitate alterations in the connections of either the armature coils or the magnet coils. If serious mechanical stresses are to be avoided, these methods can only be employed with machines having very large numbers of poles, and even then the magnetic conditions are not accurately the same as those which exist at normal full-load. The following method, known as the "intermittent short-circuit and open-circuit method," or, briefly, the "intermittent method," involves no change whatever in the connections of the machine, and requires the expenditure of only sufficient energy to cover the losses of the machine, and yet every part of the alternator reaches the same temperature as it would after an actual full-load heating test. The method involves a previous knowledge of the separate losses of the machine, but these are, in any case, determined in the ordinary course of a systematic test.

**149. Intermittent method of making a heating test.** Suppose a certain machine has at full-load: a friction loss of 10 kw.; an armature copper loss of 20 kw.; and an iron loss of 100 kw. In the course of an hour's run at full-load the loss of energy will be: $10 \times 60 = 600$ kw-min. as friction; $20 \times 60 = 1{,}200$ kw-min. as copper loss in armature; $100 \times 60 = 6{,}000$ kw-min. as iron loss.

Let the machine run for 5 min. with the armature short-circuited, and at such an armature current that the armature copper loss is 60 kw., *i.e.*, at a current equal to $\sqrt{3}$ times the normal current. Next let the machine run for a further 10 min. with open armature circuit, but overexcited, so as to give an iron loss of 150 kw. This adjustment is made according to indications of the wattmeter on the driving motor, allowance being made for other losses, such as losses in the motor itself and friction of the alternator and the driving mechanism. If this cycle of operations is repeated regularly throughout the time of the test, it is obvious that $10 \times 60 = 600$ kw-min. will be lost in friction per hr.; $60 \times 20 = 1{,}200$ kw-min. will be lost in armature copper per hr.; $150 \times 40 = 6{,}000$ kw-min. will be lost in the iron per hr., or, exactly the same loss in each case as would have occurred under normal full-load in the same time. There is still the loss in the magnet windings to be considered. During the short-circuit test this is less, and during the open-circuit test it is greater than the normal, so that on the average it does not differ very greatly from the normal. If, however, great exactness in this respect is required it is obtained as shown in Par. 150.

**150. Further refinements of the intermittent method of making a heating test.** In the above example one-third of the time of each period of the test was devoted to the short-circuit test, and two-thirds to the open-circuit test. These proportions may, however, be changed at will, and by varying the short-circuit current and the overexcitation correspondingly, the total energy expended in the armature copper and iron per hr. may be kept at the right value, while the average exciting energy will have some value other than before. Except in very extreme cases, *e.g.*, in the case of alternators which require only a very small change in excitation between no-load and full-load, and which at the same time have a very low value for the ratio

$$\frac{\text{short-circuit current at full excitation}}{\text{normal full-load current}};$$

it is always possible so to adjust the two time intervals, that while keeping the copper loss and the iron loss per hr. at the correct value, the exciting loss per hr. has practically the same value as at normal full-load. Exactness is, however, unnecessary, as, in any case, a simple calcula-

* These methods are described by Mordey, *Journ.* I. E. E., Vol. XXII, 1893. Behrend, *Elec. World and Engineer*, Vol. XLII, Oct. 31 and Nov. 14, 1903.

Digitized by Google

tion will always enable the temperature rise of a field coil at the correct full-load loss to be determined from the temperature rise measured at some slightly different known number of watts.

**151. Pre-heating, before a test, with excessive currents.** A great saving in the time required to test a large generator may be effected by applying excessive losses for a sufficient time before the commencement of the periodic test above described, and thus heating the machine up to the maximum temperature it is likely to reach. The continuation of the intermittent test (Par. 149 and 150) for a very few hours will then, even in the case of the largest generators, allow the steady final temperature to be reached.

**152. The calculation of the copper losses** requires measurements of the resistance of the windings. When the windings are of sufficiently high resistance and low current capacity, the resistance is most readily determined from the pressure in volts required to maintain through the winding a known current. When the winding is of very low resistance and of large current-carrying capacity, the best method generally consists in connecting it in series with a conductor of a known resistance of the same order of magnitude, and comparing by a millivoltmeter the pressure across each of the resistances when carrying a considerable current. Obviously the value of the current need not be known.

**153. The friction and windage losses and the iron losses** should be measured by driving the alternator by a motor of which the efficiency is known for all values of the input. The motor should, if practicable, be directly coupled to the alternator. This will usually be impracticable, hence, in most cases an allowance must be made for the loss in the driving belt. The capacity of this motor should preferably not be much greater than sufficient to drive the alternator on open circuit with full excitation of its field circuit. The motor will thus always be operating either well on toward its full-load, or else at overloads, and its efficiency will be high and fairly constant. The measurements should not be made until the alternator has been run for a sufficiently long time to bring its bearings into good condition. Then the speed of the small motor should, by shunt control or otherwise, be adjusted at such a value as to drive the alternator at its rated speed. Suppose that the input to the small motor is then $E$ volts and $I$ amp., and that its efficiency at this input is 75 per cent. Then the friction and windage loss of the alternator amounts to $0.75 \times E \times I$. The field of the alternator should then be excited at constantly increasing values, and readings should be made of the volts and amp. input to the driving motor (whose speed must be maintained constant), and of the terminal voltage of the alternator on open circuit. This last reading permits of obtaining data for the saturation curve, during the progress of the core-loss test. If, at that value of the saturation corresponding to normal voltage of the alternator at no-load, the input to the driving motor is $E_1$ volts, and $I_1$ amp., and its efficiency under these conditions is 80 per cent., then the friction losses and the core loss together amount to $0.80 \times E_1 \times I_1$, and the core loss amounts to $0.80\,E_1I_1 - 0.75\,EI$. The core loss at various other excitations should also be obtained.

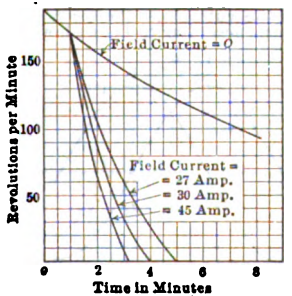

FIG. 72.—Friction and core-loss retardation curves of an alternator.

**154. Retardation test** for friction and core loss. The machine is brought up to speed and the driving belt or motor then disconnected. The machine then gradually decreases in speed, the speed being read on a tachometer at regular intervals, and a curve plotted showing the speed as a function of the time. If $K$ is the moment of inertia of the rotating element in lb. ft.$^2$ and $S_1$ and $S_2$ are successive speed readings in rev. per min. at the beginning and end of a time $T$ seconds; then when the field ex-

Digitized by Google

citation is zero the friction losses in watts are given by the formula $P = [K \times 0.148(S_1^2 - S_2^2)] + (2T)$. If the field is excited, the machine will come to rest in less time, and a larger loss $P_1$ will be obtained. This consists of the friction and core losses. By taking several curves with varying excitation, the core loss at different voltages may be determined, and a curve for core loss and voltage obtained. A typical set of retardation curves for a three-phase 350-kv-a., 2,100-volt, 50-cycle, 176-rev. per min. alternator is given in Fig. 72.

## INDUCTION MACHINES

### GENERAL THEORY OF THE POLYPHASE INDUCTION MOTOR

**155. Principle of operation.** The polyphase induction motor consists of a primary structure and a secondary structure. The former is usually stationary, supporting coils symmetrically on its inner periphery. These

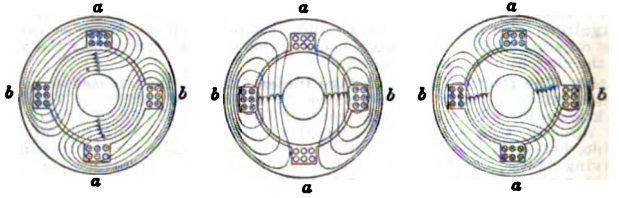

FIG. 73. FIG. 74. FIG. 75.

FIGS. 73, 74, 75.—Diagrams of coils and magnetic flux in elementary two-phase two-pole induction motor.

coils are displaced in space (*e.g.*, two coils at right angles, or three at 60 deg.), and in them flow currents of the same frequency, but differing symmetrically in phase, *e.g.*, two at 90 deg., or three at 60 deg.). The secondary (usually rotatable) structure carries properly displaced short-circuited coils. The polyphase currents in the primary structure produce a revolving field.* As this cuts across the secondary conductors, currents are induced therein which, according to Lenz's law, are in such direction as to oppose the cause. That is to say, these secondary currents react on the revolving magnetic flux in such a way as to drag the secondary conductors and structure along with the rotating flux.

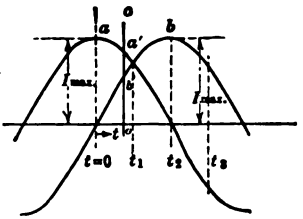

FIG. 76.—Current-time curves for two-phase indicator-motor windings.

**156. Revolving field.** Fig. 73 shows a two-phase, two-pole, laminated-iron stator with each coil imbedded in a pair of slots. The flux shown corresponds to the instant $t_1$ in Fig 76. Figs. 74 and 75 show the flux corresponding to instants $t_2$ and $t_3$ in Fig. 76. The rotation or progression of the flux is obvious. If in place of the two-pole field of Fig. 73, we substitute a multipolar field, as many cycles of current variation will be required for one revolution of the magnetic field, as there are pairs of poles.

**157. Synchronous speed and slip.** The speed of the revolving field is called the synchronous speed, and the percentage by which the rotor or secondary falls below this speed is called the slip. If $2p$ represents the number of poles, and $f$ the frequency, the synchronous speed in rev. per min. is $R_s = 60f/p$.

* See any elementary text-book on this subject.

**158. Induction motor similar to direct-current shunt-wound motor.** Synchronous speed in an induction motor corresponds to that speed of a direct-current shunt-wound motor at which the counter e.m.f. is just equal to the impressed e.m.f. In fact the mechanical characteristics of the two motors are practically identical, within their working range. For example, starting with the rotor at nearly synchronous speed, assume a load to be applied at the pulley. The speed will drop; the rate at which the secondary conductors cut (*or slip* backward through) the revolving field, will increase; and the induced e.m.f., the current and the torque will increase until the increase in torque just meets the demand imposed by the load. All of this is analogous to the operation of a shunt motor, but there is one important difference. In the induction motor, as the slip increases, the frequency and therefore the leakage reactance of the secondary increases in direct proportion. This results in an increasing lag of the secondary current behind the flux by which its e.m.f. is induced, and means, therefore, a decreasing effectiveness of the secondary current in torque production.

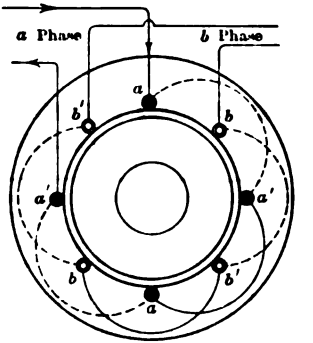

FIG. 77.—Four-pole, two-phase induction motor with one station slot per pole per phase.

**159. Stalling torque.** Beyond a certain point, the increase of slip and slip voltage with load, is accompanied by an almost proportional increase of impedance, so that the secondary current ceases to increase with the slip at the same time that its torque effectiveness is decreasing. Thus there is a point or slip beyond which the torque actually decreases, causing the motor to stop. In a good motor this stalling torque is largely in excess of the torque at its rated load.*

**160. Primary or stator winding.** Fig. 77 shows a two-phase, four-pole stator with one slot per pole per phase.

**161. Distribution of primary winding.** On the score of tooth-tip or zigzag leakage (Par. 195), the concentrated or unicoil windings shown in

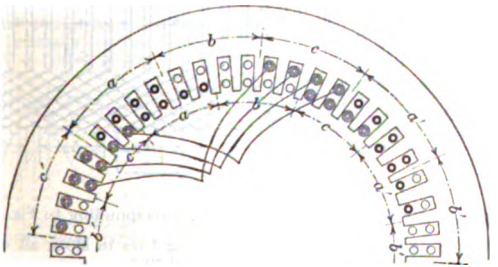

FIG. 78.—Diagram of a four-pole five-sixth pitch winding for the stator of a three-phase induction motor.

Figs. 73 and 77 are objectionable, and it becomes even more necessary than in the case of the synchronous machine, to distribute the winding among several slots per pole per phase, from two to eight or more, but rarely less than three.

* See provisions regarding stalling torque in the A. I. E. E. Standardisation Rules (Sec. 24).

Digitized by Google

**162. Classification of stator windings.** Stator windings correspond exactly with the armature windings of synchronous machines (Par. **16 to 22**), and, as in that case, the two-layer lap winding is much the commonest type. Figs. 78 and 79 relate to a three-phase, four-pole, two-layer lap winding, with five-sixths pitch (ten slots in 12) and four slots per pole per phase. The bottom and top slot belts labelled *a* comprise the back-connected (*through* the paper) conductors of the *a* phase, those labelled *a'* the outward-connected (*from* the paper) conductors of the same phase; similarly with the *b* and *c* phases. Several coil ends of the *c* phase are shown diagrammatically. Fig. 79 shows a diagrammatic developed end view of the phase belts.

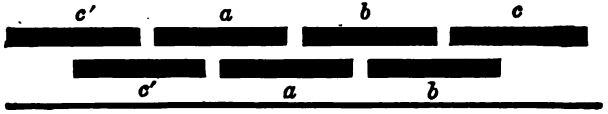

FIG. 79.—Sectional diagrammatic development of the phase belts of the winding of Fig. 78.

A developed diagram of connections of the windings of Fig. 78 is shown in Fig. 80, where the dotted lines indicate the bottom-slot coil sides or the lower layer.

**163. Secondary or rotor windings.** These may consist of any symmetrical arrangement of short-circuited conductors in which series-connected conductors do not generate opposing e.m.fs. There are three principal types.

(a) **Phase wound**, like the primary, except that the phases are short-circuited or brought out through collector rings for insertion of starting resistance. The number of phases need not be the same as for the primary, and is usually 3.

(b) **Independently short-circuited loops or coils.** The two active sides of each loop are approximately 180 magnetic deg. apart.

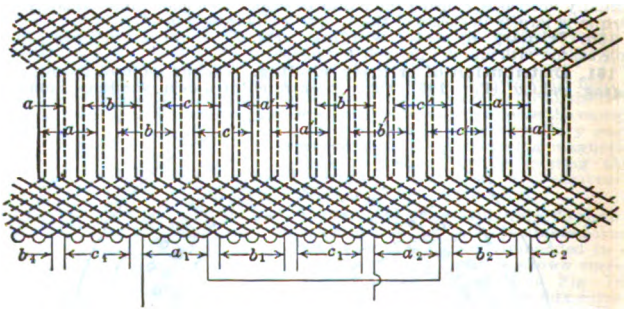

FIG. 80.—Developed winding diagram corresponding to Fig. 78.

(c) **Squirrel cage**, consisting of conducting bars in slots, all connected at the ends by conducting rings, called the end rings.

In (b) and (c) there are as many phases as there are slots per pole.

**164. Peripheral distribution of current, m.m.f. and gap flux.** The cylindrical shell comprising the currents on the two sides of the air gap, and the magnetic flux crossing the gap may be considered as the active region of any generator or motor, and the analysis of the phenomena in this region will yield most of the vital characteristics of the machine. Neglecting the localisation of current in the slots and taking the average amperes per in. of periphery in each phase belt, the heavy full-line curves of Fig. 81 show the primary current distribution of a three-phase full-pitch winding at the

Digitized by Google

instants *m*, *n*, and *o* of Fig. 82. The axis of each curve in Fig. 81 represents the air gap, and the sections *a*, *b*, *c*, etc., the primary phase belts along one side of the gap. The broken-line curves of Fig. 81 show the m.m.fs. around the flux paths crossing the gap at each point. That is, the maximum ordinate of the m.m.f. wave at *p* or *p'* is proportional to the ampere-turns with which the longest flux path *pp'* (shown dotted) is linked. This is the sum of the ampere-turns of belts *c'*, *a*, and *b*. Similarly the ordinate at *q* or *q'* represents the ampere-turns of the belt *a* with which the path *qq'* links.

Neglecting the ampere-turns consumed in the iron part of these paths, the ordinates of the m.m.f. curve may be used to designate the magnetic potential differences across the gap at the several points. But since the gap is normally

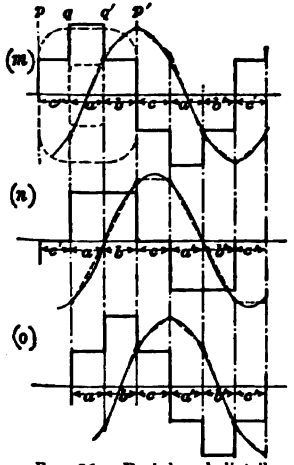

FIG. 81.—Peripheral distribution of primary current and m.m.f. in a three-phase, full-pitch stator.

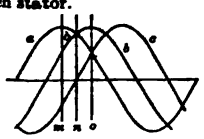

FIG. 82.—Current-time curves for a three-phase winding.

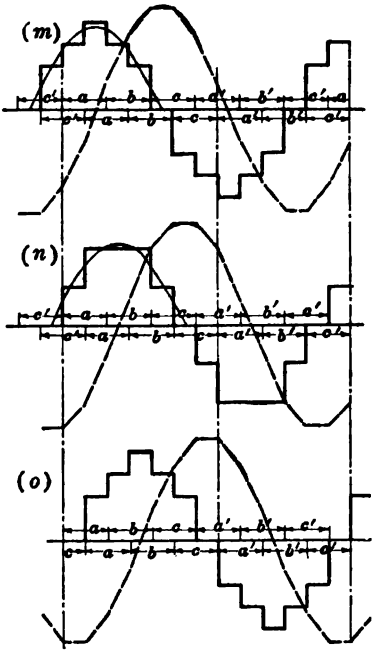

FIG. 83.—Peripheral distribution of primary current and m.m.f. in a three-phase, five-sixths pitch stator winding.

of constant radial depth, the broken-line curves may be used also to represent the flux-density in the gap, the disturbing effect of the slot openings being neglected. If the concentration of the current in slots be considered, the *m.m.f.* curves would be of the step variety with a step for every tooth. Fig. 83 is the same as Fig. 81 except that the coil pitch has been reduced to five-sixths. In both Figs. 81 and 83, it will be observed that although the gap-flux-distribution curve changes its shape slightly, it is nearly sinusoidal, and that it progresses or rotates uniformly around the gap periphery. Sine-waves are shown for comparison. The shape of the current distribution curve changes more than that of the m.m.f. curve, but it progresses or

Digitized by Google

rotates at the same velocity. The changes of the flux curve, in shape and magnitude, are graphically analysed for full-pitch windings on pages 380–390 of the 2nd edition of Hobart's "Electric Motors." See also pages 120–125 of Hobart's "Design of Polyphase Generators and Motors," especially the diagram on page 123.

**166. Flux and current distribution for two-phase motors.** In a two-phase motor the belts are broader, the steps in the current and flux-distribution curves larger and the change of shape from instant to instant greater. The breaking up of the belts by usng a five-sixths pitch in the three-phase, or a three-quarters pitch in the quarter-phase motor, reduces these variations and smooths out the curves.

**166. Secondary current and m.m.f. relations.** Since the secondary *e.m.f.* is induced by cutting the gap flux, the resulting secondary current will bear a definite space-phase relation to the gap flux (Fig. 84), and its *m.m.f.* will be sinusoidally distributed around the gap. Also, since the primary (or stator) counter *e.m.f.* is nearly equal to the impressed *e.m.f.* and is induced by the rotation of the gap flux at synchronous speed, the flux will be nearly constant in magnitude, for constant impressed *e.m.f.* Thus the resultant of the primary and secondary *m.m.fs.* will be nearly constant and such as to produce the constant flux.

**167. Similarity of the induction motor to the transformer.** Thus the induction motor is similar to a transformer. In fact, at standstill, it is a short-circuited polyphase transformer with distributed windings, and an air gap between primary and secondary. Like the transformer, the induction motor may be regarded as having three fluxes. These are the main flux, linked with both primary and secondary; and the primary and secondary leakage fluxes, linked only with the primary and secondary respectively (Par. 193 to 198). Owing to the air gap in the main magnetic circuit, the quadrature **magnetizing current** of the induction motor is several times as large as in a closed magnetic circuit transformer, even though the air gap is usually reduced to the lowest safe mechanical clearance. Because of this same air gap and the separation it makes necessary between the primary and secondary windings, the **leakage reactance** is also several times as large as in the average transformer.

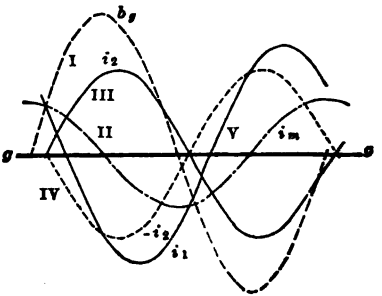

FIG. 84.—Peripheral distribution of flux and currents in polyphase induction motor.

Thus the **power-factor** of the induction motor is inherently low as compared with the closed magnetic circuit transformer. Representative power-factors for motors of various frequencies, speeds, and outputs, are given in Figs. 119 and 121.

**168. Revolving flux and current distribution.** Assume that the gap flux and currents are distributed sinusoidally around the gap periphery at any instant, and that the rotor conductors are independently short-circuited. Referring to Fig. 84, *gg* is the developed air-gap line; above this line is the primary or stator, and below it is the secondary or rotor. Flux directed upward in the figure is thus directed outward from secondary to primary; this direction will be called positive and will be indicated in the curve by ordinates measured upward from the gap line. Current directed outward from the paper will be called positive and will be so indicated in the curves. The flux and the rotor are assumed to be revolving counter-clockwise (right to left), the rotor less rapidly than the flux; therefore the rotor revolves clockwise with respect to the flux (left to right in the figure). Curve *I* represents by its ordinates the space variation of flux density, $b_g$, crossing the gap. This sinusoidal flux distribution will be assumed as the starting

Digitized by Google

point. Its magnitude is approximately constant and dependent upon the impressed e.m.f. as in the transformer.

**169. Magnetising Current $i_m$.** In order to supply the corresponding distribution of magnetic potential difference, there will be required a sinusoidal distribution of magnetising current $i_m$, such as shown by curve *II*, Fig. 84. See also $I_m$, Fig. 86. The *m.m.f.* (and therefore the flux) distribution must be the integral of the magnetising-current distribution, and differ in space phase by 90 deg.

**170. Secondary or slip e.m.f., $e'_2$.** As the rotor conductors slip backward (left to right, Fig. 84) through the flux, each will experience an e.m.f. proportional (at fixed slip velocity) to the density of the flux at the position in question. Curve *I* may therefore be used to designate at proper scale the e.m.fs., $e'_2$, induced in the several secondary conductors (plotted according to the positions of the conductors in which the e.m.fs. are induced) at any given instant. Curve *I* may also be used to designate the e.m.f. of a single conductor as it moves through the flux, plotted according to the position of that conductor with respect to the flux.

**171. The secondary current $i_2$** will have a time lag with respect to $e'_2$, because of the secondary leakage reactance; its curve will therefore be displaced to the right, curve *III*, Fig. 84, since each conductor will have moved with respect to the flux during the lag interval between the occurrence of corresponding values of $e'_2$ and $i_2$.

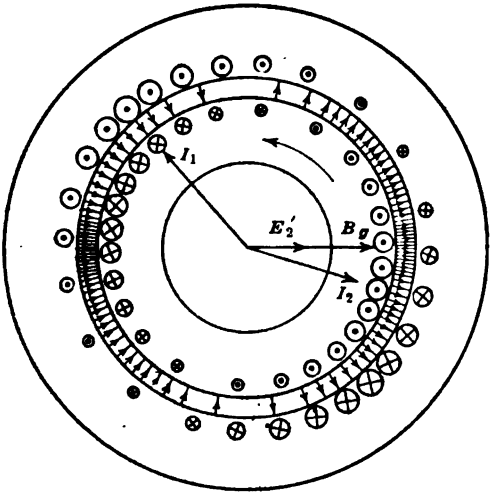

FIG. 85.—Semipictorial representation of vector quantities involved in induction-motor operation.

**172. Primary current $i_1$.** The primary current density at any point of the periphery and at any instant, must then be such as to neutralize the *m.m.f.* of the secondary current and also to supply the magnetising current $i_m$. It will then be the sum of $i_m$ and $-i_2$ at that same point and instant (see curve *V*).

**173. Basis for vector diagram of induction motor.** It should be remembered that the curves of Fig. 84 represent primarily space distributions of the several variables at a given instant, and that these distributions revolve at synchronous speed around the gap periphery, keeping the same relative

Digitized by Google

positions or space phases for a given condition of load. These distributio are shown in semipictorial fashion in Fig. 85, where the vectors $B_e$, and $I_1$ point to the positions at which the maximum positive values of the quantities occur, at the instant shown.

*The time variation of all these quantities with respect to any particular poi or conductor on the primary side of the gap, will be sinusoidal at primary fr quency, and at secondary or slip frequency with respect to any point or co ductor on the secondary structure. It is only from this point of view and wi this understanding that it is possible to represent consistently primary an secondary variables on the same vector diagram.*

Thus the vectors of Fig. 85 may be used to represent not only the spac phases, but also the time phases of the several variables, when viewed fro either stationary or rotating structure, it being obvious that there is no fixe phase difference between the primary current in a particular *primary* con ductor, and the secondary current of very different frequency in a particu lar *secondary* conductor. By extending the vector diagram of Fig. 85 w obtain the complete space and time vector diagram of the induction moto in Fig. 86.

**174. Analysis of vector diagram.** $E'_1$ is that part of the impressed e.m.f. to neutralise the counter e.m.f. induced by the mutual flux $\Phi$, the direction of the vector $\Phi$ being that of the plane of the coil when it links the maximum flux, just as the direction of $B_g$ is that of the plane of the coil when it is cutting the densest gap flux and generating the maximum e.m.f. $I_m$ is the magnetising current and $I_{c+h}$ the core loss energy current, their

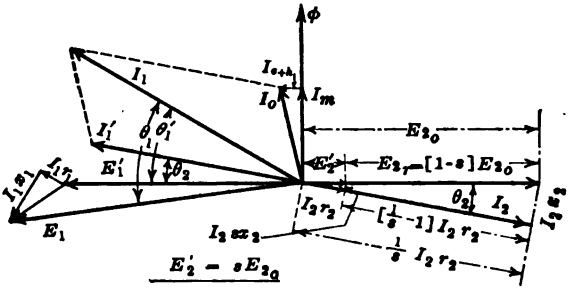

FIG. 86.—Vector diagram for induction motor.

sum being $I_s$, commonly called the exciting current. Assuming all secondary quantities reduced to primary turns, $E_{2_0} = E'_1$ is the e.m.f. that would be induced in the secondary at standstill. The actual secondary induced e.m.f. is $E'_2$, which equals $sE_{2_0}$, where $s$ is the slip. $E_{2_r} = (1-s)E_{2_0}$, is the e.m.f. that would be induced in the secondary if revolving in the flux $\Phi$ at its actual speed, and will be called the speed e.m.f. $x_2$ is the secondary leakage reactance at primary frequency, and $sx_2$ is the same at slip frequency. The secondary resistance is $r_2$. The secondary current is therefore:

$$I_2 = \frac{E'_2}{\sqrt{r_2^2 + s^2 x_2^2}} = \frac{E_{2_0}}{\sqrt{\left(\frac{r_2}{s}\right)^2 + x_2^2}} \quad \text{(amp.)} \qquad (37)$$

(The two e.m.f. triangles corresponding to these equations are shown in Fig. 86.) $I'_1$ is the part of the primary current to neutralise $I_2$, and $I_1$ the total primary current. $I_1 r_1$ and $I_1 x_1$ are the e.m.fs. consumed by primary resistance and leakage reactance respectively. $E_1$ is the impressed e.m.f.

**175. The corresponding equivalent circuit scheme** is given in Fig. 87, which is exactly that of a transformer with a non-inductive load resistance $(r_2/s)(1-s)$.

Digitized by Google

**176. Direct-current shunt-motor analogy.** It is obvious that the speed voltage $E_{2r}$ consumed by the fictitious load resistance is the representative of the rotational power transformed, including output and friction losses, and is exactly analogous to the counter e.m.f. of a direct-current motor. Similarly, $E_{2s}$ corresponds to the impressed e.m.f. and $E_2'$ to the net or resistance consumed e.m.f. of the direct-current motor.

**177. Power analysis.** The following analysis of the power $P_1$, delivered to the motor primary, may be readily followed from either Fig. 86 or Fig. 87. Designating the number of phases by $p'$, the primary power per phase is

$$\frac{P_1}{p'} = I_1E_1\cos\theta_1 = I_1^2r_1 + E'_1I_1\cos\theta_1$$

$$= I_1^2r_1 + I_{e+h}E'_1 + (E'_1I'_1\cos\theta_2 = E_{2s}I_2\cos\theta_2)$$

$$= I_1^2r_1 + I_{e+h}E'_1 + I_2^2r_2 + E_{2r}I_2\cos\theta_2$$

$$= I_1^2r_1 + I_{e+h}E'_1 + I_2^2r_2 + I_2^2\left(\frac{r_2}{S}\right)(1-s) \quad \text{(watts)} \qquad (38)$$

In words, $P_1$ = primary copper loss + core loss + secondary copper loss + output (including friction), and $P'_2 = p'E'_1I'_1\cos\theta_2 = p'E_{2s}I_2\cos\theta_2$ is the power transmitted across the air gap. $P'_2$ is the product of the torque of the revolving field by its angular velocity, or $P'_2 = 0.142TR_s$ where $T$ = torque in lb. ft. and $R_s$ = rev. per min. at synchronism.

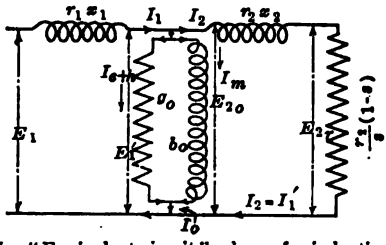

FIG. 87.—"Equivalent circuit" scheme for induction motor.

**178. Torque.** But the torque received by the rotor must be the same as that delivered by the revolving field, and neglecting friction, this is all delivered at the pulley. Thus the output (including friction) is $P_2 = 0.142TR_r$ where $R_r$ = rotor rev. per min.

$$P_2 = P'_2\frac{R_r}{R_s} = (1-s)P'_2, \text{ and } P'_2 - P_2 = sP'_2 = p'I_2^2r \quad \text{(watts)} \qquad (39)$$

The slip is thus a measure of the secondary copper loss, and the motor is analogous to a friction coupling in which the friction torque between the two faces is proportional to the slip. Since $R_s$ is constant, the torque is directly proportional to $P'_2$; in fact, $P'_2$ is frequently referred to as the torque in synchronous watts, meaning the power-equivalent of the torque at synchronous speed, measured in watts. Thus

$$T_w = P'_2 = p'E_{2s}I_2\cos\theta_2 \quad \text{(watts)} \qquad (40)$$

and

$$T = 7.05\frac{P'_2}{R_s} = 7.05p'E_{2s}I_2\cos\theta_2 \times \frac{1}{R_s} \quad \text{(lb. ft.)} \qquad (41)$$

$IT = I_2\cos\theta_2$ is called the torque current.

## INDUCTION-MOTOR CHARACTERISTICS

**179. Exact formulas.** From the vector diagram of Fig. 86 or from the equivalent circuit scheme of Fig. 87, exact formulas may be easily developed for the currents, fluxes, voltages, powers, torque, power-factor, efficiency, etc., all in terms of $E_1$, $s$, and the constants of the motor; but these are such complicated functions of the slip as to be too cumbersome for quick computation.

Digitized by Google

although none too accurate for poor motors. By a poor motor is not meant necessarily a poor design, but a poor result which may be due to difficult specifications, *e.g.*, relatively low speed or relatively high frequency.

**180. Approximate working formulæ for torque, output and starting current.** For most purposes the following are sufficiently accurate. It will be observed that the constants of the exciting circuit do not enter; this is due to the approximation, which is equivalent to neglecting the exciting current as far as it affects the quantities considered.

**Torque**

$$T = \frac{7.05}{R_s} \cdot \frac{p' E_{1s}^2 \frac{r_2}{s}}{\left(r_1 + \frac{r_2}{s}\right)^2 + (x_1 + x_2)^2} \quad \text{(lb. ft.)} \qquad (42)$$

**Slip corresponding to maximum torque**

$${}_sT_{max} = \frac{r_2}{\sqrt{r_1^2 + (x_1 + x_2)^2}} \quad \text{(lb. ft.)} \qquad (43)$$

**Maximum or stalling torque**

$$T_{max} = \frac{7.05}{R_s} \cdot \frac{p' E_1^2}{2\left[r_1 + \sqrt{r_1^2 + (x_1 + x_2)^2}\right]} \quad \text{(lb. ft.)} \qquad (44)$$

**Starting torque**

$$T_s = \frac{7.05}{R_s} \cdot \frac{p' r_2 E_1^2}{(r_1 + r_2)^2 + (x_1 + x_2)^2} \quad \text{(lb. ft.)} \qquad (45)$$

**Starting current**

$$I_s = \frac{E_1}{\sqrt{(r_1 + r_2)^2 + (x_1 + x_2)^2}} \quad \text{(amps.)} \qquad (46)$$

$$T_s = \frac{7.05}{R_s} p' I_s^2 r_2 \qquad (47)$$

**$r_2$ corresponding to maximum starting torque**

$$r_2 = \sqrt{r_1^2 + (x_1 + x_2)^2} \quad \text{(ohms)} \qquad (48)$$

**Output**

$$P_2 = p' E_1^2 \cdot \frac{\frac{r_2}{s}(1 - s)}{\left(r_1 + \frac{r_2}{s}\right)^2 + (x_1 + x_2)^2} \quad \text{(watts)} \qquad (49)$$

**Maximum output, i.e., stalling load**

$$P_{2max} = \frac{p' E_1^2}{2\left[(r_1 + r_2) + \sqrt{(r_1 + r_2)^2 + (x_1 + x_2)^2}\right]} \quad \text{(watts)} \qquad (50)$$

**Slip corresponding to maximum output**

$${}_sP_{2max} = \frac{r_2}{r_2 + \sqrt{(r_1 + r_2)^2 + (x_1 + x_2)^2}} \qquad (51)$$

These approximations are fairly accurate except where the exciting current is large. As the primary current and power-factor are both largely affected by the approximation involved in the formulæ given above, their formulæ are not given. They can be most easily obtained from the circle diagram.

**181. The method of percentages.** For the purpose of discussing the operating characteristics of an induction machine, as well as in connection with problems involved in its design, the following method of valuing its constants will be found very convenient. Referring to Figs. 86 and 88, and remembering that $E_{20} = E_1'$, let $I_1 r_1 / E_1' = q_{r1}$; $I_1 x_1 / E_1' = q_{x_1}$; $I_2 r_2 / E_1' = q_{r2}$; $I_2 x_2 / E_1' = q_{x2}$; $q_x = q_{x1} + q_{x2}$. Let $I_2 \cos \theta_2 = I_T$ be called the torque current, since it is the component of $I_2$ which is effective in producing torque. $I_m / I_T = q_m$; $I_{e+h} / I_T = q_e$; $I_o / I_T = q_o$; $q = q_x + q_m$ = total quadra-

Digitized by Google

ture component. $I_2/I_T = q_2$; $I_1/I_T = q_1$; $E_1/E'_1 = q_{E_1}$; $T_{max}/T_f = q_{T_{max}}$, where $T_f$ = full-load torque; etc. All currents, voltages, etc., correspond to full-load unless otherwise specified. These could have been expressed in terms of $E_1$ and $I_1$ rather than in terms of $E'_1$ and $I_T$, but for most purposes the latter will be found more convenient. Formulæ for these percentages are given in Par. 182 to 189. The torque formulæ given above, as well as many others involving vital relationships between induction-motor variables, may be written in terms of these percentages, with the advantage that while the actual constants $r_1, x_1$, etc., have values depending upon the size and voltage of the motor, and are not easily compared as between

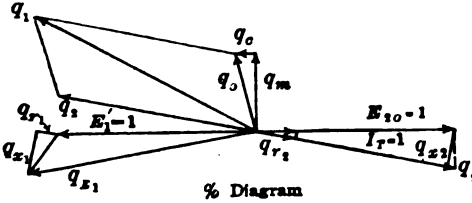

FIG. 88.—Percentage vector diagram for induction motor.

two motors of different voltages or outputs, the percentage values are immediately comparable and are direct measures of all the vital relationships. This advantage is particularly marked in the case of approximate formulæ, where their simplicity enables one to compute mentally most of the important characteristics of an induction motor, starting with only two or three of these percentages. Moreover, it is a very simple matter to memorize the range of these percentages in standard machines, as well as the effect of unusual specifications, and thus hold in one's head vital information concerning machines of all sizes and voltages, which would otherwise fill many long tables.

**183. Power-factor.** Referring to Fig. 88, the power-factor ($\cos \theta_1$) is obtained by resolving each vector along and perpendicular to $E_1$. The exact formula is complicated, but a fair approximation is

$$\text{power-factor} = \frac{1}{\sqrt{1+q^2}} \qquad (52)$$

In Fig. 89, curve III is plotted from Eq. 52 and curve I from the complete equation with the following assumptions; $q_{r1} = 0.02$; $q_c = 0.04$; and $q_{x1} = 1.3 q_{x2}$.

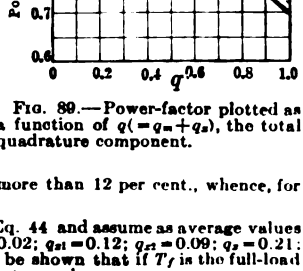

FIG. 89.—Power-factor plotted as a function of $q(=q_m+q_2)$, the total quadrature component.

**184. Slip.** $s = q_{r2} + \sqrt{1 - q_{x2}^2}$. But in a reasonably good motor, $q_{x2}$ is not more than 12 per cent., whence, for all practical purposes $s = q_{r2}$.

**184. Stalling torque.** Start with Eq. 44 and assume as average values for a good motor of moderate size: $q_{r1} = 0.02$; $q_{x1} = 0.12$; $q_{x2} = 0.09$; $q_2 = 0.21$; $q_m = 0.25$; $q_c = 0.04$. Then it can easily be shown that if $T_f$ is the full-load torque, the per cent. maximum or stalling torque is

$$q_{T_{max}} = T_{max} \div T_f = 1 + (k_T q_2) \qquad \text{(approx.)} \qquad (53)$$

where $k_T$ varies from 1.85 for a motor with high, to 2 in a motor with low

Digitized by Google

power-factor. $T_{max}/T_f$ is plotted against $q_x$ in Fig. 90, for $k_T = 1.9$. From which, if 2 is the lower limit for $T_{max}/T_f$, $q_x$ must not be more than 0.26.

**185. Per cent. stalling torque.** Hobart gives the per cent. stalling torque in terms of $\sigma$ (Par. 207) and $q_m$ as follows ("Polyphase Generators and

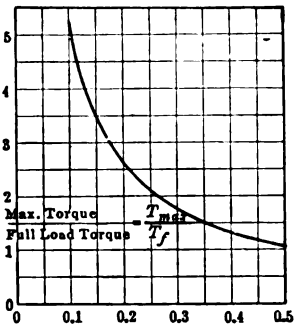

FIG. 90.—Ratio of maximum torque to full-load torque, plotted as a function of the total percentage reactance drop.

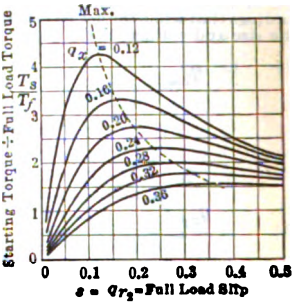

FIG. 91.—Ratio of starting torque to full-load torque.

Motors," page 190): $qT_{max} = 0.4\ q_m/\sigma$. This is equivalent to $k_T = 2.3$, (since $\sigma = 0.93\ q_m q_x$), which is considerably larger than 1.9 used in Fig. 90.

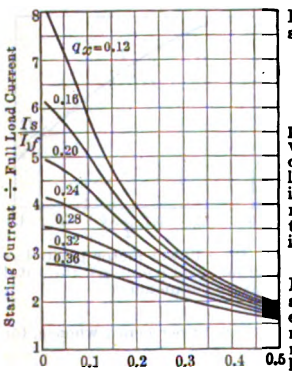

FIG. 92.—Ratio of starting current to full-load current, plotted as a function of the full-load slip.

**186. Starting torque.** Beginning with Eq. 45, it can be shown that the per cent. starting torque is

$$qT_s = T_s \div T_f = \frac{1.20 q_{r2}}{(q_{r1}+q_{r2})^2 + q_x^2} \quad \text{(approximately)} \qquad (54)$$

Assuming $q_{r1} = 0.02$, the ratio $T_s/T_f$ is plotted against $q_{r2}$ in Fig. 91, for several values of $q_x$ within the range of commercial motors; from which the quantitative limitations in the starting torque of the induction motor are obvious. The maximum value of the ratio $T_s/T_f$ is obviously the same as $T_{max}/T_f$ and occurs when $q_{r2}$ is about equal to $q_x$.

**187. Secondary starting resistance.** Except in machines of very low reactance, a large starting torque is only possible by employing a comparatively large secondary resistance. In a squirrel-cage motor this means large secondary copper loss and large slip. The desirable resistance of a squirrel-cage secondary is usually a compromise between the low-resistance needed for speed regulation and efficiency, and the high resistance desired for starting torque, the relative weight given to these two considerations being determined by the specifications. In a wound-rotor machine, resistance can be inserted in the secondary for starting and cut out after the machine has attained speed.

Digitized by Google

**188. Starting current.** Neglecting the exciting current, the starting current is given by Eq. 46; this may be transformed to

$$I_s = I_T \frac{1.1}{\sqrt{(q_{r1}+q_{r2})^2+q_x^2}} = \frac{I_{1f}}{\sqrt{q_r^2+q_x^2}} \quad \text{(approx.) (amp.)} \quad (55)$$

or

$$q_{I_s} = I_s + I_{1f} = 1 + \left(\sqrt{q_r^2+q_x^2}\right) \quad (56)$$

The ratio $(I_s/I_{1f})$ of the starting current to the full-load primary current is plotted against $q_{r2}$ for several values of $q_x$ in Fig 92; $q_{r1}$ is again taken =0.02. It will appear from an inspection of Fig. 92 that the starting current taken by a squirrel-cage induction motor at full voltage is too large to be tolerated in the case of large motors. In such cases compensators or induction starters are used to reduce the voltage during the starting period.

**189. Compensator starting of squirrel-cage motors.** To find the per cent. starting torque for a given maximum allowable line current, let $T_{sc}$ = starting torque with compensator; $T_f$ = full-load torque; $I_l$ = line current at starting and $I_f$ = full-load current.

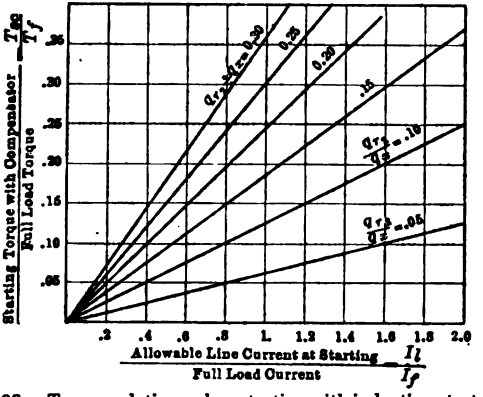

FIG. 93.—Torque relations when starting with induction starter or compensator.

Then from Eq. 54 and 56 and the compensator relations, it can be shown that

$$q_{T_{sc}} = \frac{T_{sc}}{T_f} = \frac{I_l}{I_f} \quad \frac{1.25q_{r2}}{\sqrt{q_r^2+q_x^2}} \quad \text{(approx.)} \quad (57)$$

This is plotted in Fig. 93 for several values of the ratio $(q_{r2}/q_x)$. As an example, take a large squirrel-cage motor which must be started without drawing more than full-load current from the line. Assume $q_x = 0.20$ and $q_{r2} = 0.02$. Then $T_{sc}/T_f = (1.25 \times 0.02)/0.201 = 0.124$ or one-eighth of full-load torque.

**190. Deep rotor bars for starting.** The curves of Figs. 91 to 93 show in a striking manner the inherently poor starting qualities of squirrel-cage induction motors, except when a large full-load slip is allowed. This defect may be eliminated in some degree by a very ingenious device consisting in the use of very deep rotor slots and bars, which gives a high apparent resistance and low reactance at starting, and the reverse near synchronism. The only drawback is the reduced stalling torque; but in many cases there is ample margin. The resistance multiplier is 0.35 × depth of bar in inches × √frequency. See Hobart's "Design of Polyphase Generators and Motors," p. 168.

**191. Summary.** Figs. 89 and 93 show clearly the relations of all the vital operating characteristics (except heating) of induction motors of whatever size, frequency, or voltage, to a very few constants; and although the results are only approximate, they will give a fair quantitatave grasp of induction motor characteristics. The largest errors will occur in small or low-speed motors with large exciting currents.

The most important of these characteristics are almost wholly determined by $q_m$, $q_x$, and $q_{r1}$. The other $q$'s may be approximated with sufficient accuracy, since they play only a small part, and a considerable error in their approximation does not seriously affect the results. Of $q_m$, $q_x$, and $q_{r2}$ the last may be given almost any desired value without much affecting the other constants; whereas $q_m$, and $q_x$ are intimately related to one another, to the major design constants, and to the details of design. Their computation is given below.

## MAGNETIZING CURRENT*

**192. Air gap and gap ampere-turns.** The air gap is usually reduced to a comfortable mechanical clearance, and may be taken approximately as $\delta = 0.015\sqrt[4]{\text{kw.}}$ (inches). The gap ampere-turns are computed in the same manner as for the alternator (see Par. 40, Figs. 39 and 40). Designate by $a_1$ and $a_2$, respectively, the primary and secondary slot-contraction factors; by $K_1 = a_1 a_2$, the combined slot-contraction factor; by $K_d$ the corresponding air-duct contraction factor; and by $K_2$ the ratio of gap ampere-turns to total ampere-turns. $K_2$ varies from 0.9 in slow-speed high-frequency machines to 0.7 in high-speed, low-frequency machines. These are, however, outside limits, and 0.8 may ordinarily be assumed as a fair average for a rough approximation. Then the total ampere-turns for the longest complete magnetic circuit is $Ni = (0.626\mathfrak{B}\delta)/K_1K_2K_d$.

Let $\Delta$ = peripheral loading corresponding to torque current $I_T$ (Fig. 88); $\mathfrak{B}$ = maximum or crest value of equivalent sine-wave of gap-flux distribution; $v$ = peripheral velocity (ft. per sec.) of revolving field; for $k_b$ and $k_p$ see Par. 28–31 (synchronous machines).

Then, assuming that the magnetising current is equivalent to a sinusoidal distribution of current density, of root-mean-square value $\Delta_m$, $\Delta_m = 0.116\mathfrak{B}\delta/(k_b k_p K_1 K_2 K_d v)$ and the per cent. or fractional magnetising current is

$$q_m = \Delta_m/\Delta = 0.116\mathfrak{B}\delta/(k_b k_p K_1 K_2 K_d \Delta v) \qquad (58)$$

For a three-phase motor $k_b = 0.955$. For five-sixths pitch $k_p = 0.96$. For open-slot stator and nearly closed-slot rotor, $K_1 = 0.65$ (approx.). For a well-ducted motor $K_d = 0.9$. For a 60-cycle motor, $K_2 = 0.8$ (approx.). Then, roughly, $q_m = (0.27\mathfrak{B}\delta f)/(\Delta v)$.

## LEAKAGE REACTANCE*

**193. The four elements of the leakage flux are computed** as if separate from the main flux, whereas they are for the most part only distortional as to the main flux. Consider the phase-belt as the unit, Figs. 94 and 95.

**194. Slot leakage.*** This is the cross-slot flux (Fig. 94). The inch permeance or flux linkage (lines) per amp.-in. of primary phase-belt is (see Fig. 42)

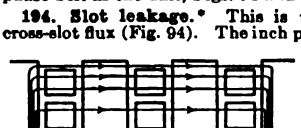

FIG. 94.—Illustrating cross-slot leakage flux.

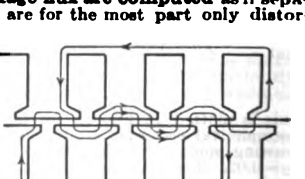

FIG. 95.—Illustrating tooth-tip leakage.

$$\varphi_{sl} = \frac{3.2}{N_{spp}}\left(\frac{1}{3}\frac{d_1}{w_s} + \frac{d_2}{w_s} + \frac{2d_3}{w_s + w_{so}} + \frac{d_4}{w_{so}}\right) \qquad (59)$$

* Transactions American Institute Electrical Engineers, Vol. XXIV, 1905, p. 338. Also Vol. XXVI, p. 1245.

Digitized by Google

The total slot-linkage per amp. in. of phase-belt is

$$\varphi_{sb} = \varphi_{sb1} + \varphi_{sb2} \qquad (60)$$

where $N_{spp}$ = slots per pole per phase, and $N_s$ the number of slots.

**195. Tooth-tip or zigzag leakage.** See Fig. 95. The flux linkage (lines) per amp. in. of belt, for both primary and secondary is $\varphi_{tb} = A\tau_t + \delta N_{spp}$ where $\tau_t$ is the average tooth pitch, primary and secondary, and $A = 2.13[(a_1 + a_2 - 1)/2]^2$ is plotted in Fig. 96.

The above values of $\varphi_{sb}$ and $\varphi_{tb}$ are for *full-pitch* and should be multiplied by $k_{ps}$ and $k_{pt}$ respectively (Figs. 97 and 98) for *fractional pitch* windings.

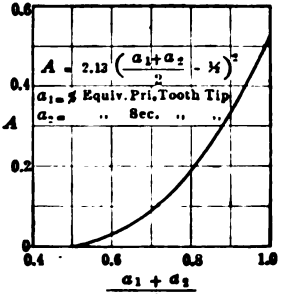

FIG. 96.—Average per cent. tooth-tip overlap "A," vs. average per cent. equivalent tooth-tip.

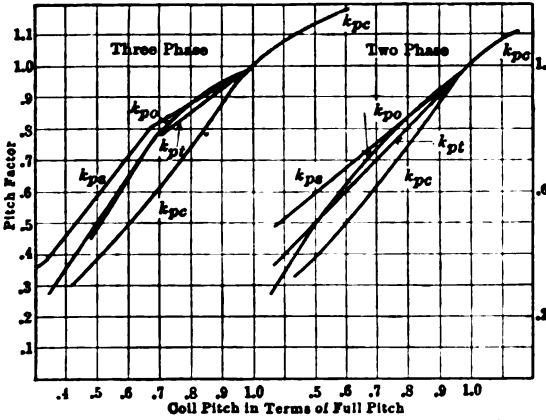
**196. Coil-end leakage.** A crude but helpful picture of this flux is shown in Fig. 99. Charging all coil-end leakage to the primary, the resulting lines per amp. in. of phase belt bundle, $\varphi_f$, is given in Fig. 100 for three-phase motors with various coil pitches, both for squirrel-cage and phase-wound rotors.

When reduced to the basis of the active phase-belt, $\varphi_f$ becomes $\varphi_{fb} = k_2 k_f \varphi_f = k_2 K_f$ where $k_f$ = ratio of length of one coil end to pole pitch, $k_2 = \tau/l$, and $K_f$ $(= k_f \varphi_f)$ is plotted in Fig. 101 against the coil pitch, for squirrel-cage and wound-rotor motors. The higher values correspond to high-voltage machines where the coil overhang is longer, or to machines with the coil ends bent back, thus allowing more room for leakage between primary and secondary coil ends (Fig. 99). In the case of the squirrel-cage rotor, $\varphi_f$ depends upon the type and position of the end ring.



FIGS. 97, 98.—Leakage-reactance pitch factors; $k_{ps}$ for slot-leakage, $k_{pt}$ for tooth-tip leakage, $k_{pe}$ for coil-end leakage.

For a simple ring at the ends of the bars, the lowest value of $\varphi_f$ corresponds to a position out from the core, equal to seven-tenths of the primary coil projection. That is, the primary coil-end currents act like a single circumferential current at the seven-tenths point (see the cross in Fig. 99, which

Digitized by Google

indicates a circumferential current backward through the paper). If the ring is set radially inward nearer the shaft, $\varphi_f$ may be increased as much as 50 per cent. (see the upper curve). Or, if the end ring is placed nearer the core, $\varphi_f$ may be considerably increased (25 or 30 per cent.).

**197. Belt-leakage.*** For three-phase motors and full-pitch windings the flux linkage per amp-in. of belt is

$$\varphi B_3 = k_B K_1 K_2 K_d \tau + 314\delta = K_B \tau + 314\delta \qquad (61)$$

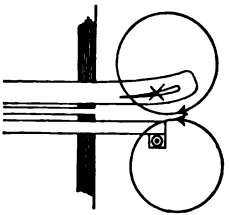


FIG. 99.—Coil-end leakage paths.

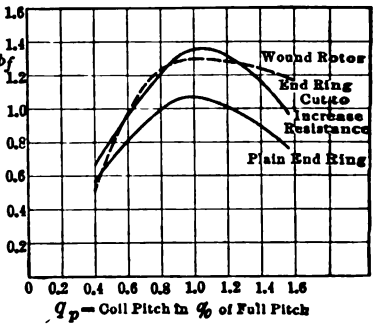

FIG. 100.—Coil-end flux linkage lines per ampere-inch of phase-belt bundle (primary and secondary) as a function of the coil pitch.

where $k_B$ is given in Fig. 102 and $K_B = k_B K_1 K_2 K_d$. For a two-phase motor with full-pitch winding

$$\varphi B_2 = K_B \tau + 105\delta \qquad (61a)$$

For a squirrel-cage motor, take values about one-half of these values.

A coil pitch of five-sixths in a three-phase, or of three quarters in a two-phase motor, reduces the belt width, permeance of the mean paths, conductors per belt, and mean phase-difference, each to one-half. The belt reactance is thereby reduced to about one-sixteenth of its full-pitch value.

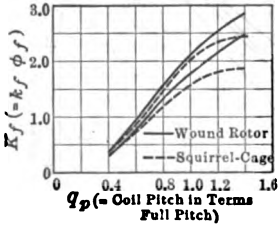

FIG. 101.—Coil-end leakage constant.

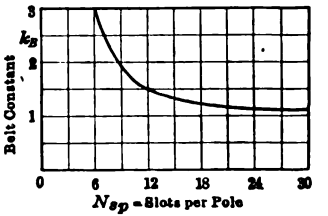

FIG. 102.—Belt leakage constant.

**198. Summary.** Adding together the several $\varphi$'s with their proper pitch factors the total reactance for a three-phase motor is

$$x_3 = 2\pi f 2 p l N^2_{epp} 10^{-8} (k_{p1}\varphi_{3b} + k_{p1}\varphi_{1b} + k_3 K_f + K_B \tau + 314\delta) \qquad (62)$$

where $N_{epp}$ = conductors per pole per phase.

* See *Transactions* International Electrical Congress, St. Louis, 1904; ————, Vol. I, page 706.

Digitized by Google

A much more convenient form for many purposes is the per cent. reactance volts ($Ix_2 + E'_1 = e_{x2}$).

$$e_{x2} = 0.78 k_p S \frac{\Delta f}{\mathfrak{B}} + 28.1 k_p \frac{A}{\delta N_{sp}^2} \frac{\Delta \mathfrak{v}}{\mathfrak{B} f} + 1.56 K_f k_2 \frac{\Delta}{\mathfrak{B}} + 0.03 K B \frac{\Delta \mathfrak{v}}{\delta f \mathfrak{B}} \quad (62a)$$

where $N_{sp}$ = slots per pole, and $S = \tau \varphi_{sb} + 3$. $S$ varies from 6 to 18 with an average of 10 to 12.

The several terms in Eq. 62a represent, in order, the slot, tooth-tip, coil end and belt leakages.

These equations can be much simplified for any particular type of motor by assuming numerical values for some of the minor constants; but the use of the complete expressions involves only a few minutes in computation, and has the advantage of keeping before the mind the factors upon which the reactance depends. Approximations which are quite allowable in one type of machine are dangerous in another.

## CIRCLE DIAGRAM

**199. The circle diagram.** If the constants of an induction motor are really constant it can be proved that the locus of the primary current vector,

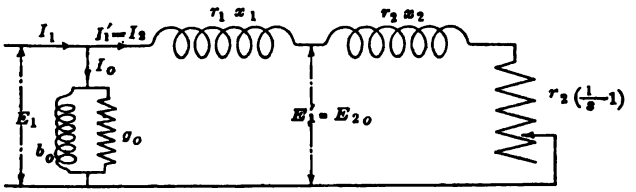

FIG. 103.—Approximate equivalent circuit diagram of induction motor.

plotted with respect to a constant impressed e.m.f., is a circle. For the purpose of approximate calculation and still more for the visualization of induction motor characteristics, the circle diagram is invaluable, and is widely employed by Continental and British designers. The simplest form

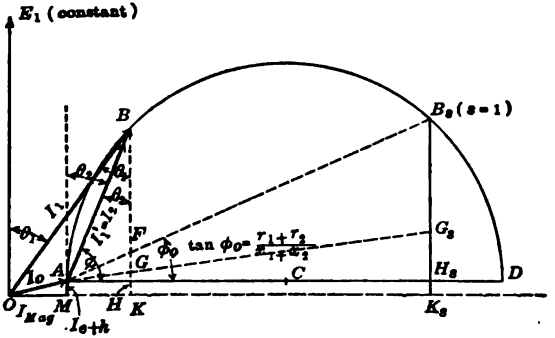

FIG. 104.—Approx. circle diagram corresponding to Fig. 103.

is that based upon the approximate equivalent circuit scheme of Fig. 103, which differs from the equivalent circuit scheme of Fig. 87 in having the exciting-current circuit connected outside of the primary. This renders the load-current circuit independent of $I_o$, and leaves it with a constant reactance ($x_{12} = x_1 + x_2$) and a variable resistance $r_{12} = r_1 + (r_2/s)$ depending upon the slip. When a constant voltage is impressed upon such a circuit and the

Digitized by Google

resistance varied (variable $s$), the locus of the current is a circle. The exciting current must be added to obtain the total current.

The corresponding diagram is shown in Fig. 104. If this diagram be rotated counter-clockwise until $E_1$ is slightly below the horizontal on the left, it will correspond with the left-hand side of the regular vector diagram, Fig. 86. The diameter of the circle in Fig. 104 is $E_1/(x_1+x_2)$. $B_s$ is the short-circuit or standstill point; tan $\varphi_s = \frac{r_1+r_2}{x_1+x_2}$, and $B_sG_s+G_sH_s=r_2+r_1$.

The approximation involved in this diagram is such that serious errors are not introduced in the case of a good motor, *i.e.*, a motor with low exciting current and low reactance; but the errors become serious in poor motors.

**200. Note concerning interpretation of approximate circle diagram.** In what follows $E_1$ and $I_1$ are the volts and amperes of a single phase. If $E_1$ be the line voltage multiplied by $\sqrt{3}$, and $I_1$ the line current, $p'$ should be omitted from all expressions for power and torque.

**201. The impressed power** is, $P_1 = p'E_1I_1 \cos\theta_1 = p'E_1 \times \overline{BK}$; but since $p'E_1$ is constant, $\overline{BK}$ is proportional to and a direct measure of the power delivered to the motor; *i.e.*, a scale of watts or kilowatts can be chosen according to which $\overline{BK}$ indicates directly the impressed power, $P_1$.

**202. Losses, output, torque and slip.** According to the same scale $\overline{HK}$ indicates the core loss, $p'E_1I_{e+h} = P_{e+h}$. If $I_0$ is measured when the motor is running light, the corresponding power will include the friction loss, in addition to core loss, and since the friction loss is practically constant,

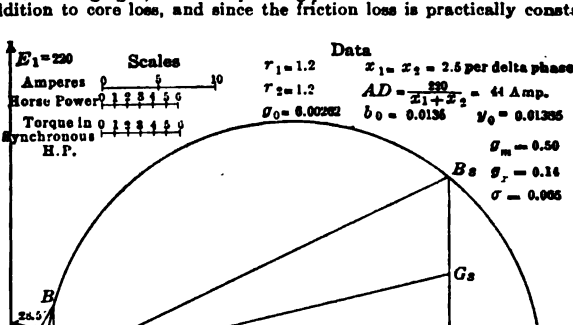

FIG. 105.—Approx. circle diagram for a 5-h.p. three phase, 6-pole, 220-volt, delta-connected induction motor.

it could be charged to the exciting circuit (Fig. 103), by increasing $g_0$ in the proper degree. It will be so taken here, *i.e.*, that $\overline{HK}$ represents core and friction loss. Similarly $\overline{HG}$ represents the primary copper loss, $\overline{GF}$ the secondary copper loss, $\overline{FB}$ the output ($P_2$), $\overline{GB}$ the power transmitted across the air gap (*i.e.*, the torque in synchronous watts) and $\overline{GF}+\overline{GB}$ the slip.

**203. Efficiency (Par. 210-216).** The efficiency is $P_2/P_1 = BF/BK$.

**204. Power-factor (Par. 216).** The power-factor, $\cos\theta_1$, may be readily determined from the diagram by drawing a unit circle about $O$ and measuring the vertical intercept of the $I_1$ vector on this unit circle.

Thus for any point $B$ on the circle, all the important variables of the induction motor may be readily determined from the circle diagram.

**205. Experimental determination of circle diagram.** The experimental data necessary is,

Digitized by Google

(a) Amperes and watts at normal voltage when the motor is running light. This gives the $I_o = \overline{OA}$ of Fig. 104. Thus the point $A$ may be located, starting with $O$ as the origin, and $E_1$ vertical.

(b) Amperes and watts at normal voltage with rotor blocked. It is sometimes necessary to make this test at reduced voltage owing to the excessive currents which would flow at full voltage, and to change the results to the full voltage equivalent. This will locate the point $B_s$, which together with $A$ determines the circle, the diameter being assumed horizontal through $A$.

(c) The resistance of the primary winding.

All of these tests, particularly the last two, should of course be made at or near the normal working temperature of the motor.

The diagram thus experimentally determined, expresses with a very fair degree of accuracy the relations between all the important variables of the motor.

Fig. 105 shows the approximate circle diagram drawn to scale for a 5-h.p., three-phase, 6-pole, 220-volt induction motor, and Fig. 106 shows the characteristic curves obtained therefrom.

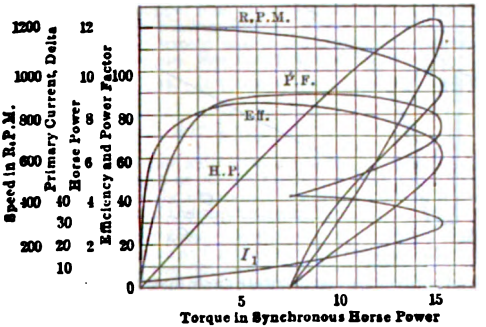

FIG. 106.—Characteristic curves from Fig. 105.

**206. Exact circle diagram.** Starting with the complete equivalent circuit scheme (Fig. 87), it is easy to prove that the locus of the primary current is a circle whose radius is $E_1/2x_d$, and the coordinates of whose centre with respect to $O$, are $E_1 b_o$ and $E_1 g_o$, where

$$x_d = x_1 + x_2 + \frac{x_1^2}{z_0^2}(x_0 + x_2) + \frac{2x_2}{z_0^2}(r_1 r_0 + x_1 x_0) \quad \text{(ohms)} \quad (63)$$

$$b_o = \frac{\frac{1}{2} + b_0 x_2}{x_d} + \frac{x_1(b_0 + x_1 y_0^2)}{x_d} \quad \text{(mhos)} \quad (64)$$

$$g_o = \frac{g_0 x_2}{x_d} + \frac{r_1(b_0 + x_1 y_0^2)}{x_d} \quad \text{(mhos)} \quad (65)$$

$E_1 b_o$ is the abscissa and $E_1 g_o$ the ordinate of the centre, starting with $E_1$ vertical. The approximate and accurate circle diagrams of a good motor are shown to scale in Fig. 107, both computed from the same constants. If the points $B_s$ and $A$ are determined experimentally, then the only inaccuracy of the approximate circle, is due to the fact that its centre would be located on the horizontal line through $B_0$ rather than at the real centre, which is usually a little above the line, see Fig. 107, where the broken-line circle was drawn through $B_0$ and $B_s$ (observed), with centre $C_A$ on horizontal line through $B_s$. Fig. 107 also shows the loci of the other variables.

**207. Leakage factor or circle ratio.** This is defined in various ways by various authors. Roughly it is the ratio of the total leakage permeance to the main flux-path permeance, or the ratio of the magnetising current to the diameter of the circle. Sometimes it is stated as the ratio of magnet-

Digitized by Google

ising current to the short-circuit current, but this is inaccurate for motors with high secondary resistances. It is dependent upon the machine proportions and independent of the load.

For all practical purposes it is

$$\sigma = 0.93 q_m q_s = \frac{3.95 S \delta}{\tau^2} + \frac{3.95 A}{N_{sp}^2} + \frac{1.32 K_f \delta}{l} + 0.0052 \qquad (66)$$

For values of $S$, $A$ and $K_f$ see Par. **195** to **198** and Figs. 96 to 101. $S$ varies from 6 to 18 with an average of 10 to 12; $A$ from 0.2 for open slots

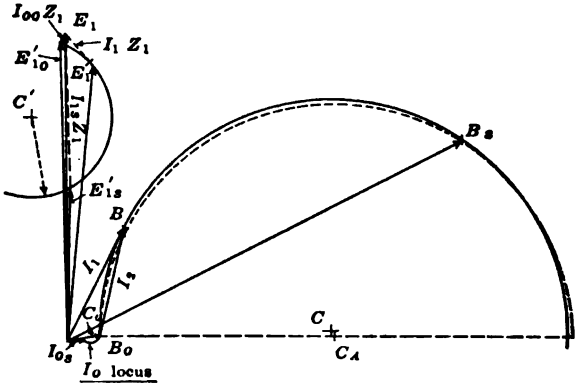

FIG. 107.—Approximate and accurate circle diagram of an induction motor.

on one side of gap to 0.42 for nearly closed slots on both sides, and $K_f$ from 1.5 in good squirrel-cage motors to 2.2 in slip ring motors, see Fig. 101.

Kierstead has proposed a somewhat simpler though less rational formula; it is

$$\sigma = C \left( \frac{0.079}{l} + \frac{0.19}{\tau} + \frac{3}{N^2_{sp}} \right) \qquad (67)$$

where $C$ varies with the air gap according to the accompanying table

| $\delta$ ..... | 0.024 | 0.032 | 0.039 | 0.047 | 0.055 | 0.063 | 0.071 | 0.079 | 0.087 | 0.095 |
|---|---|---|---|---|---|---|---|---|---|---|
| $C$..... | 0.71 | 0.88 | 0.99 | 1.09 | 1.17 | 1.25 | 1.31 | 1.39 | 1.45 | 1.52 |

Of these equations, Eq. 66 gives results quite as accurate as the average test results can check, and for all types of machines. Eq. 67 gives fair results for the majority of standard machines, although inaccurate for extreme cases.

The leakage factor or circle ratio is much used by European designers. Reference may be made to Hobart's "Electric Motors" and "Design of Polyphase Generators and Motors" where the designing of induction motors is explained with the assistance of the circle diagram in a simpler though less accurate manner than is described in Par. **243** to **259** below.

**208. Maximum power-factor.** In terms of $\sigma$, it is given by various authors, thus

$$\text{Maximum power-factor} = \frac{1}{1+2\sigma} \qquad (68)$$

$$\text{Maximum power-factor} = \frac{1-\sigma}{1+\sigma} \qquad (69)$$

Digitized by Google

The accuracy and meaning of either of these depend upon the method of determining or of defining $\sigma$.

## LOSSES AND EFFICIENCY

**210. Classification of losses.** The losses of an induction motor are as follows: (a) the primary copper loss; (b) the secondary copper loss; (c) the core loss; (d) friction and windage losses. The copper losses may be computed in the ordinary way, except that in the case of squirrel-cage rotors the method is not quite so obvious. See Par. 212, also Sec. 24.

**211. Primary copper loss.** In terms of the design constants and in terms of the output, it is

$$q_{r1} = \frac{(1+k_3k_f)10^8}{8.5k_3k_{p8}\mathfrak{B}m} \tag{70}$$

where $m$ is the circ. mils per amp. Owing to the lower flux density in the gap, there is a greater length of active conductor than for the synchronous alternator; but this is partly neutralized by the larger $m$ made necessary by the poorer ventilation of the short air-gap machine.

**212. Secondary copper loss.** In the case of a wound secondary, the copper loss is about the same as for the primary, for although the current is less, there is in most cases less slot section available for copper. In the case of a squirrel-cage rotor, it is usually easy to make the secondary resistance low. Unfortunately this opportunity may not ordinarily be taken advantage of, since the starting torque requirements frequently demand a relatively large value of the slip and therefore of $q_{r2}$, Par. 186 and Fig. 91.

The squirrel-cage copper loss may be computed as follows: The secondary current per bar is $I_b = \Delta_2 \tau_2$ where $\Delta_2$ is the secondary peripheral loading and $\tau_2$ the secondary tooth pitch. $I_b^2$ times the ohms per bar times the number of bars = total bar loss. The current in each end ring is $I_r = I_b$ times the number of rotor conductors per pole divided by 2.22, and the end ring loss is $I_r^2$ times total series resistance of both end rings.

**213. Core losses.** The calculation of the core losses of an induction motor is not so simple a matter as might at first appear, since, in addition to the losses in core and teeth at fundamental frequency, there are tooth frequency losses in both primary and secondary teeth, wave losses in tooth tips and losses due to breakdown of laminations. There are also sometimes, at load, eddy losses in the copper conductors, A. I. E. E., Vol. XXIV, p. 761.

**214. Calculation of core losses.** There is no simple *rational* method at present available for computing the core losses of induction motors with reasonable accuracy. The following formulæ have coefficients such that when applied to the primary teeth and core, they yield results large enough to cover the indeterminable losses, except in those cases where the tooth-frequency losses are unusually large, as with open slots on both rotor and stator.

For 60 cycles—Watts per cu. in. $= P_{60}' = 4.1(B_m/10^4)^2$.
For 25 cycles—Watts per cu. in. $= P_{25}' = 1.3(B_m/10^4)^2$. Laminations assumed to be 0.014 in. thick. Nearly all the extra losses are due to eddy currents rather than to hysteresis; hence the exponent 2 is sufficiently accurate.

The following table of data for estimating the core loss of induction motors is taken from Hobart's "Design of Polyphase Generators and Motors."

Digitized by Google

| Density in stator core (lines per sq. in.) | Core loss in stator core (watts per lb.) for various frequencies | | |

## STANDARD POLYPHASE INDUCTION MOTORS

**215. Representative power-factors and efficiencies of standard squirrel-cage motors.** The losses and efficiency of a typical 5 h.p., 60-cycle, squirrel-cage induction motor are shown plotted against the output in Fig. 108. The efficiencies of average induction machines are plotted in Fig. 109. While in any concrete case the designer has the power-factor and the efficiency within his control to a certain extent, he cannot depart widely from representative values which are inherent to the rating. The table in Par. **216** is abstracted from more elaborate tables on pp. 116 and

**217. Very large squirrel-cage motors.** The properties and costs of 1,000-h.p. 25-cycle squirrel-cage three-phase motors have been investigated for five different speeds, in order to bring out clearly the dependence of the characteristics and cost upon the rated speed. The results are set forth in the following table which is taken from p. 105 of Hobart's "Electric Propulsion of Ships" (D. Van Nostrand, New York, 1911):

| 1,000-h.p., 25-cycle, squirrel-cage, three-phase motors | | | | | |
|---|---|---|---|---|---|
| Speed, rev. per min. | Number of poles | Air-gap diameter (cm.) | Gross length of rotor core (cm.) | Max. power-factor | Total works cost in dollars |
| 125 | 24 | 238 | 53 | 0.93 | 5,000 |
| 250 | 12 | 180 | 66 | 0.94 | 3,800 |
| 375 | 8 | 138 | 76 | 0.95 | 3,200 |
| 500 | 6 | 114 | 83 | 0.96 | 2,840 |
| 750 | 4 | 87 | 95 | 0.96 | 2,500 |

From the same source ("Elec. Prop. of Ships") is taken the data in the following two tables, the first relating to designs worked out by one of the present authors for three 25-cycle, 125-r.p.m., 24-pole squirrel-cage induction motors for outputs of 100 h.p., 1,000 h.p. and 10,000 h.p., respectively, and the second relating to the complete weight, in metric tons, of five large motors.

Data of three 25-cycle, 125-r.p.m., 24-pole squirrel-cage induction motors

| | | | |
|---|---|---|---|
| Rated output (h.p.) | 100. | 1,000. | 10,000. |
| Air-gap diameter (c.m.) | 151. | 288. | 565. |
| Gross core length (c.m.) | 28. | 53. | 104. |
| Maximum power-factor | 0.90 | 0.93 | 0.91 |
| Peripheral speed (m. per sec.) | 9.8 | 18.8 | 37. |
| Total works cost (dollars) | 950. | 5,000. | 21,000. |
| Total works cost per horse-power | 9.50 | 5.0 | 2.10 |
| Total weight (metric tons) | 3.5 | 14. | 80. |

Digitized by Google

Data of complete weight (exclusive of shaft and bearings) of five 33-cycle squirrel-cage induction motors for a synchronous speed of 124 r.p.m.

| Rated output | Weight |
|---|---|
| 1,000 horse-power | 15 metric tons |
| 2,000 horse-power | 25 metric tons |
| 3,000 horse-power | 34 metric tons |
| 4,000 horse-power | 42 metric tons |
| 5,000 horse-power | 50 metric tons |

**218. Weights per horse-power.** A $\frac{1}{4}$-h.p. 1,200-r.p.m. polyphase induction motor weighs a matter of 19 lb. while a 10,000-h.p. 120-r.p.m. polyphase induction motor would weigh some 176,000 lb. It is interesting to note that while the large motor has 150,000 times the output of the smaller, it only weighs about 9,000 times as much. Moreover its speed is about one-tenth as great as that of the smaller motor.

**219. Starting apparatus for standard polyphase induction motors.** Ninety per cent. of all the induction motors built in America are of the squirrel-cage type. Whereas the squirrel-cage motor when of small size is switched directly on the line at starting, it is necessary in starting larger squirrel-cage motors to employ induction starters or else the star-delta method. Slip-ring induction motors are started by means of a rheostat connected into the rotor circuits, and gradually cut out as the motor acquires speed. With the growth of electricity-distributing net-works, it has become expedient to relax the earlier onerous requirements imposed in the matter of permissible starting currents. On some systems fairly large squirrel-cage motors are permitted to be started by switching directly upon the line without induction starters. Designs in which the "deep-slot" effect (Par. 190) is correctly employed may be started directly from the line with a more moderate rush of current, and hence are the more appropriate as regards the lesser line disturbance at starting.

**220. Induction-motor starting currents.** The currents taken by good three-phase squirrel-cage induction motors at the moment of starting, have values approximately in accordance with the following table, which corresponds to $q_s = 0.13$ and $s = q_{r_1} = 0.04$, see Figs. 91 and 92 and accompanying text.

| *A* | *B* | *C* | *D* |
|---|---|---|---|
| Pressure at motor in per cent. of line pressure | Line starting current in per cent. of full-load current | Motor starting current in per cent. of full-load current | Starting torque of motor in per cent. of its full-load running torque |
| 40 | 112 | 280 | 32 |
| 60 | 250 | 420 | 72 |
| 80 | 450 | 560 | 128 |
| 100 | 700 | 700 | 200 |

**221. Calculated starting characteristics.** The following table, taken from page 451 of the 2nd Edition of Hobart's "Electric Motors" (Whittaker & Co., London, 1910) gives the calculated starting characteristics of a 6-pole 25-cycle 200-h.p. 500-rev. per min., squirrel-cage, three-phase, induction motor.

The motor to which these last results correspond, was designed for very high efficiency and without any regard to starting torque ($q_s = 0.12$ and $s = 0.02$). Consequently, we find that when started on the six-tenth taps of the induction starter, the starting torque is only 55 per cent. of full-load running torque and the line current is practically three times full-load current, a worse result than that of the average motor corresponding to the earlier table. By employing the "deep-slot" principle in the design of 60-cycle squirrel-cage induction motors, the application of the full-line pressure at starting will be accompanied by a much smaller flow of current from the line than that shown in the table for the average motor. While the torque may

Digitized by Google

also be smaller, it will nevertheless be as great as the torque corresponding to the tap on the induction starter, which corresponds (in the average motor) the lower line current. Thus nothing is sacrificed except that the motor's power-factor will be a few per cent. lower at full-load and the customer is spared the outlay for an induction starter. Further, the operation of starting is reduced to elemental simplicity.

| Pressure at motor terminals in per cent. of normal pressure | Motor's starting current in per cent. of full-load current | Line starting current in per cent. of full-load current | Input to stator (watts) | Stator copper loss (watts) | Input to rotor (watts) | Starting torque (meter kilograms) | Starting torque in per cent. of full-load running torque |
|---|---|---|---|---|---|---|---|
| 33 | 274 | 91 | 56,600 | 33,300 | 23,300 | 44.3 | 15.1 |
| 40 | 330 | 132 | 86,000 | 48,000 | 38,000 | 72.3 | 24.3 |
| 60 | 495 | 297 | 194,000 | 108,000 | 86,000 | 164.0 | 55.0 |
| 80 | 660 | 528 | 344,000 | 192,000 | 152,000 | 289.0 | 97.0 |
| 100 | 824 | 824 | 540,000 | 299,000 | 241,000 | 455.0 | 153.0 |

## THE INDUCTION GENERATOR

**222. Theory of operation.** If a polyphase induction motor, while running light, and still connected to its supply circuit, be mechanically driven above synchronism, the slip will be negative, the secondary conductors will cut the revolving flux in the opposite direction, the secondary e.m.f. and current will reverse with respect to the flux, and the torque reaction of the secondary current will oppose the rotation. This means mechanical power absorbed and a reversal of the direction of power flow across the air gap, i.e., generator action. A little consideration will show that the torque characteristic above synchronism will be approximately symmetrical with that below synchronism, referred to the point of synchronism, see Fig. 111.

**223. Circle diagram of induction generator.** The characteristics of the induction generator can be most easily determined from the circle diagram. For this purpose we may still use the induction-motor approximate-equivalent circuit scheme of Fig. 103 with the understanding that $s$ is negative which means an *apparent* negative reactance $sx_2$, and an *apparent* negative resistance $(r_2/s)(1-s)$. This means that the power delivered to this resistance is negative, and simply an electrical equivalent of the source of mechanical driving power. Upon this basis, it is evident that the locus of the extremity of $I_1$ is a circle for the induction generator as well as for the induction motor, as there is no abrupt change in the vector diagram when $s$ passes through zero.

**224. Interpretation of circle diagram.** The approximate circle diagram of the induction generator is given in Fig. 110, where the notation corresponds to that of Fig. 103 for the induction motor. The principal characteristics derived from the circle diagram are shown in Fig. 111. Referring to Fig. 110, $\overline{FB}$ represents the total power delivered to the generator (shaft-friction, windage, and rotor-core loss excluded); $\overline{FG}$ represents the rotor copper loss, $\overline{GB}$ the total power transmitted across the air gap to the stator; $\overline{GH}$ the stator copper loss; $\overline{HK}$ the stator-core loss; and $\overline{KB}$ the output $E_g I_1 \cos \theta_g$. The slip is $s = \overline{FG}/\overline{GB}$.

**225. Power-factor and excitation.** Thus the induction machine driven above synchronism, pumps power back into the line, the amount depending upon the slip. But the power-factor of the output is fixed, not by the nature of the load but by the slip and the constants of the machine itself. The induction machine always carries a quadrature current when operating either as motor or as generator. It may be said to receive a quadrature lagging current, or to deliver a quadrature leading current. This quadrature current is the excitation of the machine, a part $I_m$ for the main flux, and the remainder (or its equivalent in quadrature volt amperes) for

Digitized by Google

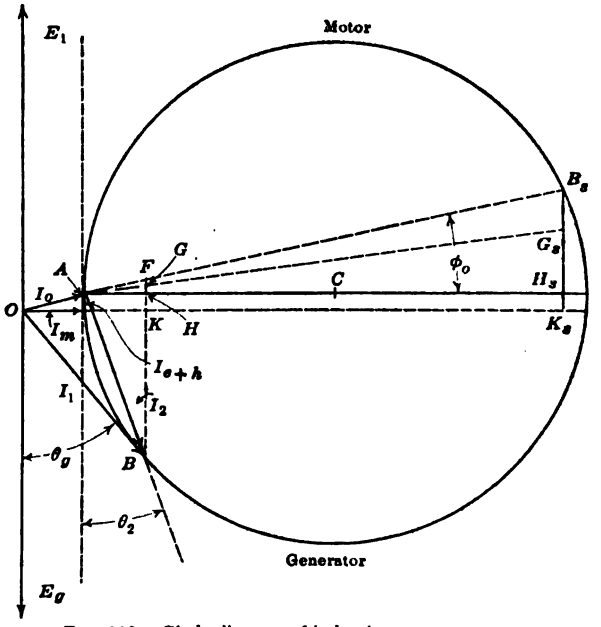

FIG. 110.—Circle diagram of induction generator.

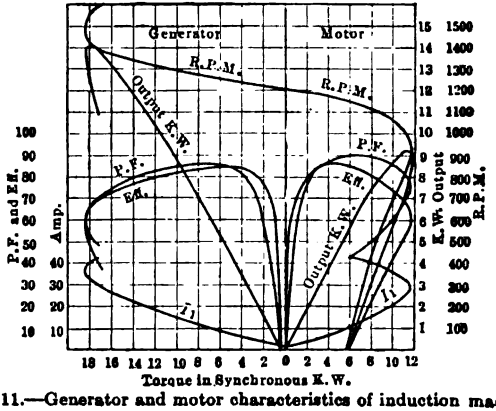

FIG. 111.—Generator and motor characteristics of induction machine.

Digitized by Google

the leakage fluxes. This exciting current is absolutely necessary to the operation of the machine, and must be supplied from the line in just as real a sense in the case of generator operation, as in the case of motor operation.

**226. Condenser excitation.** An interesting though uncommercial method of supplying this excitation is by means of condensers. With condenser excitation an induction generator acts very much like a direct-current shunt-wound generator, except that it has a separate characteristic curve for each power-factor.

The amount of capacitance required for the excitation of a large induction generator is somewhat appalling. *E.g.*, even a very large induction generator with the best constants will require about 25 per cent. reactive current at full-load; but as capacitance costs from $10 to $20 per kv-a. (higher for lower frequencies), this will add from $2.50 to $5 per kv-a. to to the cost of the induction-generator, which renders it prohibitive.

**227. Excitation from synchronous machines.** The usual arrangement for excitation is to operate induction generators in parallel with one or more synchronous machines, motors or generators, usually the latter. The synchronous machines supply not only their own excitation but also that for the induction generator, as well as the quadrature or reactive current demanded by the receiving apparatus connected to the system.

**228. Low excitation required by induction generator.** The no-load exciting current of large high-speed induction generators may be as low as 12 per cent. of the load current. The full-load lagging reactive component or what might be called the full-load excitation, is sometimes as low as 25 per cent., which means a power-factor of $1/\sqrt{1+(0.25)^2}=0.97$.

**229. Equivalent exciter capacity.** Although the excitation of the induction generator is small in ampere-turns, it is large in kv-a. since its power-factor is low. If this excitation is supplied by a special machine used for no other purpose, its kv-a. capacity must be at least 25 per cent. of that of the induction generator, whereas the capacity of the direct-current exciter for a synchronous machine is rarely more than 2 per cent., and in large machines about 1 per cent. If, however, there be enough synchronous-machine capacity installed, so that the total reactive exciting current is a small part of the load current of the synchronous machines, their resultant capacity need not be much increased. In some cases, a part of the excitation of induction machines can be supplied by the charging current of large underground cable systems. *E.g.*, the condensance of the cable system of the Interborough Rapid Transit Co. would supply full-load excitation to more than 10,000 kw. of induction generators.

**230. Voltage regulation.** The induction generator when excited from synchronous machines has no inherent regulation as to voltage, since in this respect it is quite as passive as an induction motor and depends wholly upon the voltage and corresponding excitation supplied to it by the system. In other words, the voltage must be controlled by the excitation of the synchronous machines connected to the system.

**231. Frequency regulation.** If the frequency is kept perfectly constant by the synchronous machine, induction generators can only deliver an increased output by increasing their speed and slip, see Fig. 111. If, however, the speed of an induction machine is kept constant, it can deliver more load only by a decrease in frequency, *i.e.*, by a decrease in the speed of the synchronous machines which set the frequency.

**232. Division of load.** If the induction generator be driven by a governed prime mover, its speed will drop slightly with the load, which means that the frequency and therefore the speed of the synchronous machines must drop still more. Another method of dividing the load is to drive the induction machine with an ungoverned prime mover, *e.g.*, a steam engine with fixed cut-off. In this case its output will be constant, and the speed-governed synchronous machine or machines will assume the load fluctuations, and the frequency regulation will be the same as that of the synchronous machine.

**233. Induction generators and low-pressure steam turbines.** A very good place for this method of dividing the load, is where low-pressure turbines are operated by the exhaust steam from other parallel-connected steam units. The exhaust turbines can be operated without governors, thus utilizing all the exhaust steam, and yielding the highest economy.

Digitized by Google

**234. Effect of angular variation of prime movers.** Since the division of load in the case of parallel-connected induction generators is dependent upon the relative speeds rather than upon the relative angular positions of the rotors, the relative angular displacements within one revolution of a reciprocating steam or gas engine do not produce objectionable power surges between the various generators, as frequently occurs in the case of synchronous machines. Even gas engines are quite satisfactory in this connection.

**235. Effect of e.m.f. wave shape on parallel operation.** The induction generator is largely passive as to wave shape, the latter being impressed from without, and in the presence of e.m.f. harmonics, behaves like an inductive reactance which tends to damp the harmonic currents.

**236. "Switching in."** It is not necessary to synchronize when throwing in an induction generator, since the latter has no e.m.f. until excited from the line and when so excited is always in phase. It is only necessary to get the induction machine up to speed and throw it in. As the machine cannot pick up its load until the field is established, the first rush of current is wholly exciting current and practically independent of the slip. This initial current rush is quite analogous to that experienced when switching in transformers, and is explained on the same basis. Since with large units this exciting current rush is undesirably large, reactance coils are inserted while switching in, and then cut out as soon as the steady state is reached.

**237. Hunting.** The connection between the speed of a synchronous machine and its circuit frequency is exactly analogous to a mechanical elastic coupling, and that between an induction machine and its impressed frequency, to a friction coupling in which the friction grip is proportional to the slip. The latter tends to damp out any oscillations of the system, while the former has a natural period of its own which may tend to amplify some periodic disturbances of the system. The induction machine is thus decidedly superior on the score of hunting.

**238. Short-circuits.** The short-circuit current of a synchronous alternator consists of two parts: first, the transient part limited only by the combined equivalent leakage reactance of armature and field circuits; and second, the steady part determined by the much larger synchronous reactance of the armature. The former is the serious element, from three to five times the latter. It is this transient effect that twists the armature coil ends as if they were made of rope. With the induction generator the case is quite different. There is no steady portion, since the source of exciting current disappears when the short-circuit occurs, just exactly as in the case of a direct-current shunt-wound generator. The transient effect is present, but in only small degree since, with the same flux as in the synchronous machine, the reluctance of the magnetic circuit (and hence the energy of the field) is only a fractional part (sometimes less than 10 per cent.) as great.

**239. Low-resistance squirrel-cage rotor.** Since the induction generator requires no starting torque, the rotor is always of the squirrel-cage type and of as low resistance as is consistent with the cost of the copper and the available space. This means a very low secondary-copper loss, and a slip of less than 0.5 per cent. in large machines.

**240. First cost and ventilation.** Owing to the exceedingly simple rotor construction, the induction generator would be cheaper to build than a synchronous machine of the same capacity, were it not that the short air gap makes ventilation very difficult, and the more so in those ratings which are otherwise the best suited to this type of machine. This, together with the tooth-frequency losses incident to the short air gap, makes the induction generator of doubtful superiority except in special cases. The switchboard is also simpler, and the switching operations are of reduced complexity.

**241. Best field of application for induction generators.** The specifications from which the best induction machines can be produced are high speed, large output, and low frequency, which means steam-turbine or high-head water-wheel drive in large power stations. Unfortunately these are the specifications which lead to great difficulties in ventilation, owing to the short air-gap. A large city-railway system with the load considerably made up of synchronous converters with underground-cable distribution, satisfies the conditions as to excitation.

## THE DESIGN OF INDUCTION MACHINES.

**243. Specifications.** For an induction machine the principal specifications are as follows: frequency; number of phases; speed; terminal voltage; rated output; nature of duty, continuous or intermittent service; maximum allowable temperature rise; insulation tests; stalling torque; starting torque; starting current; and, sometimes, speed regulation; power-factor; and efficiency. See also Sec. 24.

**244. Symbols.**

$A$ = tooth-tip constant for tooth-tip leakage calculation
$\sigma_1$ and $\sigma_2$ = primary and secondary slot contraction factors
$\mathfrak{G}$ = crest value of air-gap flux density (lines per sq. in.)
$\mathfrak{G}_t$ = maximum flux density in narrow part of tooth (lines per sq. in.)
$C$ = constant in Kierstadt's formula for leakage factor
$C''$ = copper section (sq. in.) per in. of periphery
$D$ = air-gap diameter (in.)
$d_s$ = slot depth (in.)
$E'_1$ = induced voltage per phase
$e''$ = volts induced per in. of active primary conductor
$f$ = frequency (cycles per sec.)
$k_c$ = copper loss per sq. in. of gap surface (watts)
$K$ = Total kw. developed = $P'_1 + 1{,}000$
$K_1 = \sigma_1\sigma_2$ = combined slot contraction factor
$K_2$ = ratio of air-gap amp-turns to total amp-turns
$K_d$ = duct contraction factor
$Kf = k_f\varphi_f$, Fig. 101
$k_l$ = ratio pole pitch to core length
$k_B$ = belt reactance factor, Fig. 102
$k_b$ = belt differential factor, Table I, Par. 81
$k_f$ = length of coil end ÷ pole pitch
$k_o$ = h.p. output per sq. in. of projected area of air-gap cylinder
$k_p$ = pitch differential factor, Fig. 22
$k_s$ = slot-reactance constant
$k_w$ = slot space-factor
$l$ = gross length of core
$N_{cpp}$ = conductors per pole per phase
$Ni$ = amp-turns
$N_{sp}$ = No. of slots per pole (average of primary and secondary)
$N_{spp}$ = slots per pole per phase
$P'_1$ = Power transmitted across air-gap
$p$ = No. of pairs of poles
$p'$ = No. of phases
$q$ = total quadrature component ($= q_m + q_s$)

Digitized by Google

$q_{il}$ = net iron length + gross core length
$q_m$ = ratio of exciting current to torque current
$q_p$ = ratio of coil pitch to pole pitch
$q_r$ = resistance drop + induced volts
$q_{so}$ = slot opening divided by tooth pitch
$q_{sw}$ = slot width + tooth pitch
$q_x$ = leakage reactance volts + induced volts
$q_{xB}$ = belt-leakage reactance volts + induced volts
$q_{xf}$ = coil-end reactance volts + induced volts
$q_{xs}$ = slot reactance volts + induced volts
$q_{xt}$ = tooth-tip leakage reactance volts + induced volts
$R$ = rev. per min.
$S$ = slot factor
$s$ = slip
$w.c.$ = total works cost (dollars)
$V_{cm}$ = total volume primary copper (circular-mil in.)
$v$ = peripheral velocity at synchronism (ft. per sec.)
$w_s$ = width of slot (in.)
$\Delta$ = torque-current amp. conductors per in. of periphery
$\Delta_1$ = primary amp. conductors per in. of periphery
$\Delta_m$ = magnetizing current amp. conductors per in. of periphery
$\delta$ = radial depth of air-gap (in.)
$\xi$ = output coefficient, h.p.
$\xi_k$ = output coefficient, kw.
$\sigma$ = leakage factor (sometimes also termed the circle ratio).
$\tau$ = pole pitch (in.)
$\tau_t$ = tooth-pitch (in.)
$\varphi_f$ = flux per amp. in. of phase belt bundle of coil-ends, Fig. 100
Subscript 1 refers to primary.
Subscript 2 refers to secondary.

**245. The output equation.** The volt-amperes induced per sq. in. of peripheral surface are, $\Delta\sigma'' = 8.5k_b k_p v B \Delta 10^{-8}$, see Par. **23**. and the kw. total developed are

$$K = 8.5 \times \pi k_b k_p \Delta v B D l 10^{-11} \quad \text{(kw.)} \tag{71}$$

This is the power $P'_1$ transmitted across the air gap and not the output, which is less by the secondary copper loss and the friction and windage loss. Assuming the latter to be about 1 per cent. and remembering that $q_{r2} = s$, we get as the horse-power output

$$\text{h.p.} = 3.55\,(1-s)\,k_b k_p \Delta \mathfrak{B} v D l 10^{-10} = k_o D l \tag{72}$$

where

$$k_o = 3.55\,(1-s) k_b k_p \Delta \mathfrak{B} v 10^{-10} \tag{73}$$

is the **specific output** in horse-power per sq. in. of projected area of the airgap cylinder. Assuming a three-phase motor ($k_b = 0.95$), of moderate capacity, with squirrel-cage rotor ($s = 0.03$), and five-sixths pitch of coils ($k_p = 0.96$),

$$k_o = 3.2 \Delta \mathfrak{B} v 10^{-10} \tag{74}$$

By substituting for $v$ in equation 72, its value $(\pi DR/720)$, we get

$$\text{h.p.} = 1.55\,(1-s) k_b k_p \Delta \mathfrak{B} D^2 R 10^{-10} = \xi D^2 R \tag{75}$$

where $\xi$ is called **output coefficient**. With the same assumptions as above,

$$\xi = 1.38 \Delta \mathfrak{B} 10^{-12} \tag{76}$$

If horse-power be replaced by kilowatts in Eq. 75,

$$\xi_k = 1.03 \Delta \mathfrak{B} 10^{-12} \tag{77}$$

Sometimes the output equation is more convenient in the form of Eq. 72, and sometimes in that of Eq. 75. Referring to Eqs. 72 and 75, and assuming $R$ specified, $\mathfrak{B}$, $\Delta$, and $v$ determine $Dl$, and $D = (720v)/(\pi R)$; or $\mathfrak{B}$ and $\Delta$ determine $D^2 l$, and $k_2 = \tau/l = (\pi D)/(2pl)$, determines the ratio of $D$ to $l$. As the cost of the machine increases approximately with $Dl$ and with $D^2 l$, $\Delta\mathfrak{B}$ should be as large as possible.

**247. Considerations affecting choice of $\mathfrak{G}$, $\tau$, and $\Delta$.** A few of the most important are given below in Par's. **248** to **256**.

**248. Tooth density limit (Par. 247).** See Par. **95**. The upper limit of $\mathfrak{G}_{tr}$ is lower than for alternators because of tooth-frequency losses. $\mathfrak{G}_{tr}$ = 85,000 to 105,000, the higher values for nearly closed slots. With open slots it is not always possible to utilize the tooth section to its limit, because of the low gap density $\mathfrak{G}$, Par. **249**.

**249. Stalling torque and power-factor (Par. 247).** The value of $\Delta/\mathfrak{G}$ must be kept below the point at which $q_{x_2}$ exceeds a value which is safe from the standpoint of stalling torque (Eqs. 53 and 62a). On the other hand, a small value of $\Delta/\mathfrak{G}$ means a large exciting current and low power-factor. (Eqs. 58 and 52.) On this account $\mathfrak{G}$ must be much smaller than for alternators, except in the case of large high-speed motors (large $\tau$). The ratio $\Delta \div \mathfrak{G}$ is thus an important one.

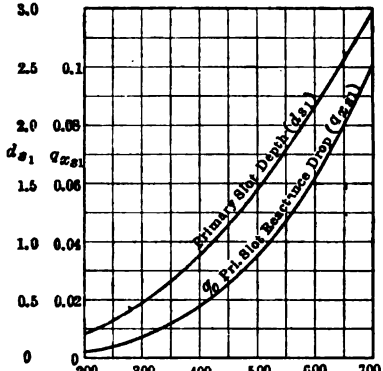

FIG. 112.—Slot depth and slot reactance as a function of the peripheral loading for a normal 5-h.p., 60-cycle open-(stator)-slot motor; $h_c = \Delta \div m$ assumed constant.

**250. Heating (Par. 247).** Same as for Alternators (Par. **96**) except that the inherent ventilation is less good because of the short air-gap.

For well-ventilated open motors a rough preliminary guide is

$$h_c = 0.4(1+0.012v) \quad (78)$$

Although the slot depth increases as $\Delta^2$ ($h_c$ constant), it would be possible to increase $\Delta$, $d_s$ and $\mathfrak{G}$ considerably beyond present limits without change of $\Delta/\mathfrak{G}$ (Par. **249**) were it not for the slot reactance, Par. **251**.

**251. Slot reactance (Par. 247).** It can be easily shown (Eq. 62a and Par. **250**) that the per cent. slot reactance volts ($q_{x_s}$) is, for constant $h_c$, proportional to $\Delta^2$, see Fig. 112. This places the upper limit on $d_s$, $\Delta$ and therefore on $\mathfrak{G}$, since $\Delta/\mathfrak{G}$ is critical, Par. **249**. Approximate values of $\Delta$ and $d_s$ for open (stator) slot motors are shown in Fig. 113.

**252. Limits of peripheral velocity.** $v$ has two principal upper limits (a) the cost and weight of copper (Par. **253**), and (b) the reactance (Par. **256**), but in this case it is the coil-end reactance in place of the slot reactance.

**253. Copper limitation of peripheral velocity (Par. 252).** As in the case of the alternator (Par. **103**) the value of $k_3$ for minimum copper is

Digitized by Google

$k_3 = 1/q_p$ (see Fig. 114) which is too small on the score of ventilation. However, as the minimum is a fairly flat one $k_3$ and $v$ may be considerably increased without seriously increasing the copper volume, to the great gain of $q_m$ and the ventilation. There is a pretty decided limit, however, since the coil-end copper increases as $v^2$ and the coil-end leakage as $v^3$. Assuming h.p. = 10, $R = 1{,}200$, $f = 60$, $\mathfrak{G} = 25{,}000$, $\Delta = 400$, $m = 600$; the weights of copper are as given in Fig. 114; $D$, $l$, $q_{sf}$ and $k_3$ ($= \tau/l$) are also shown.

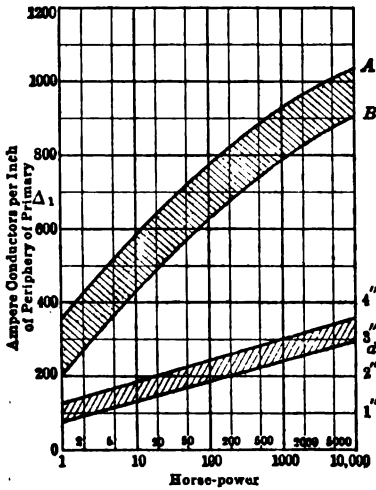

FIG. 113.—Values of peripheral loading and primary slot depth.

**254. Total cost of manufacture or works cost.** A very useful criterion of $k_3$ (and therefore of $v$), from the cost standpoint, may be obtained by the use of the following empirical formula for the total works cost (t.w.c.) taken from Hobart's "Electric Motors," 2d Edition, page 594.

$$\text{t.c.w.} = K_c D(l + 0.7 q_{sr}) \quad \text{(dollars)} \qquad (79)$$

where $K_c$ is a factor which varies but slightly with the size and proportions of the motor. By substituting, differentiating, and solving, the value of $k_3$ for a minimum *twc* is $k_3 = 0.71/q_p$.

Again the minimum is a fairly flat one and considerable leeway is available. If larger values of $v$ and $k_3$ are taken, larger $B$ and $\Delta$ may also be employed.

which, having been assumed will flatten the minimum still more and raise the desirable values of $v$ and $k_3$. Fig. 115 shows for a series of 100-h.p., 25-cycle, three-phase, squirrel-cage motors at various speeds, the influence which $k_3$ exerts on the cost, and Fig. 116 shows the corresponding values of the circle ratio.

It is instructive also to regard the cost from another standpoint. The cost of the copper and laminations is first estimated, and is designated as the cost of net effective material. If we designate the overall diameter [in inches] by $D_o$ and the gross core length [in inches] by $l$, we may take the cost of the labor, the overhead charges and the structural material, in dollars, as $(D_o^2/11) + 0.20 D_o l$. It is seen from this formula that a motor with an overall diameter of 80 in. will have an overhead cost approaching $(\overline{80}^2/11) = \$580$, as $l$ approaches zero. If $l$ is equal to 16 in., the cost to be debited to labor, overhead charges and structural material amounts to $(580 + 0.20 \times 80 \times 16) = \$836$. The total works cost is \$836 plus the outlay for the net effective material. While such methods require adjustment to the varying conditions in different works, it is nevertheless instructive to employ them.

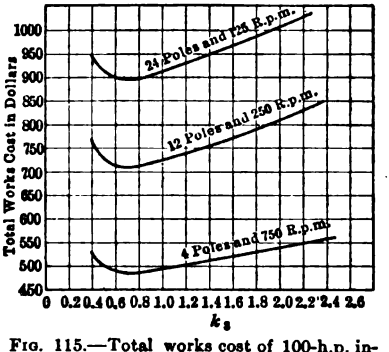

FIG. 115.—Total works cost of 100-h.p. induction motors as function of ratio pole-pitch to gross core length. Full-pitch winding assumed.

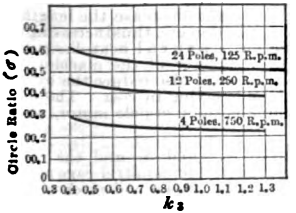

FIG. 116.—Circle ratio of induction motors as a function of ratio of pole pitch to gross core length.

From the relation $k_3 = 0.71/q_p$ for minimum total works cost, it can be shown that:

$$\tau = \frac{0.79}{q_p} \sqrt[3]{\frac{K\overline{R}}{\xi f^2}} = \frac{780}{q_p} \sqrt[3]{\frac{K\overline{R}}{\Delta \mathfrak{G} f^2}} \qquad (80)$$

Average values employed for $\tau$ are shown in Par. **255**.

**256. Coil-end-leakage limit of peripheral velocity.** The other limit to $v$ is the coil-end leakage, which is proportional to $v^2$ (see Par. 196, Eq. 62a, and remember that $k_3$ is proportional to $v^2$). $q_{zf}$ has been computed for the 10-h.p. motor of Fig. 114, and is plotted in Fig. 117. If $\Delta$ were taken larger, both the total copper and the $q_{zf}$ curves of Fig. 114 would be higher. A change in $\mathfrak{G}$ would not affect either appreciably. By using a fractional-pitch winding, both of these curves would be lowered somewhat, but there is a limit to this, owing to the necessity for more active conductors to generate the same e.m.f., or larger values of $\mathfrak{G}$ and $q_m$. A larger value for $R$ would lower both, and a larger h.p. would lower $q_{zf}$; but these are specifications. The curves of Fig. 117 show without necessary comment why $v$ may not be carried above a pretty definite upper limit for any given specifications.

**257. Fractional-pitch windings.** The use of any considerable pitch reduction or chording (beyond the five-sixths used for the curves of Figs. 118 to 121) means an increased exciting current ($q_m$) and a decreased reactance ($q_z$), other things being equal. If the motor in question were properly designed for full pitch, the pitch reduction should be accompanied by a decrease of $\mathfrak{G}$, an increase of $\Delta$ and of $v$. This will not usually increase either the power-factor or the specific output ($k_o$ or $\xi$), but rather the reverse. It will, however, increase the diameter and decrease the length of the core, thus increasing the natural heat-dissipating power of the machine. It will also reduce the overall length, which in some cases means a considerable saving in cost. The most obvious place for the fractional-pitch winding is the two-pole motor, where a pitch as low as 0.5 is sometimes used.

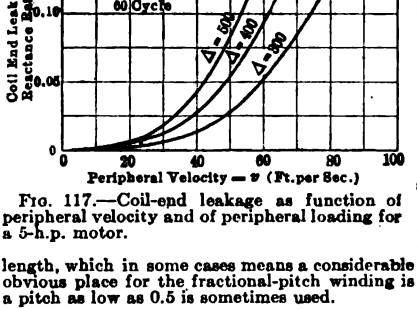

FIG. 117.—Coil-end leakage as function of peripheral velocity and of peripheral loading for a 5-h.p. motor.

**258. Data.** Figs. 118 to 121 give values of $\mathfrak{G}$, $v$ and $\Delta_1$, and the corresponding values of $q_z$, $q_m$, $q$, $k_o$, $\xi$, $k_3$, and power-factor, for squirrel-cage motors with open-stator slots and nearly closed-rotor slots, and a coil pitch of five-sixths except where otherwise designated. The curves have been computed on the following basis: $\Delta_1$ is approximated largely on the basis of heating; the values of $\mathfrak{G}$ are a compromise between first cost and stalling torque on the one hand and power-factor on the other, with more weight given to the former; $k_3$ (upon which $v$ depends) is a compromise between cost and ventilation. From these assumed values the other quantities have been computed. Both $\mathfrak{G}$ and $k_3$ are larger than are frequently met with in practice, and doubtless too large to meet some specifications.

If closed slots had been used on the stators, larger values of $\mathfrak{G}$ could have been employed to advantage, not only because of the lower reluctance of air-gap but also because of the higher allowable tooth density. This increased $\mathfrak{G}$ does not ordinarily result in an increase of power-factor, sometimes the reverse is true; but it does mean a smaller machine and less active material. This may or may not mean a cheaper machine, according as the extra cost of labor in winding is or is not made up by the saving in material. In general it would be cheaper in Europe and more expensive in this country.

Two-pole motors are rarely met with and the data for this type is given to show possibilities and the value of low coil pitch for two poles. The disadvantage is chiefly connected with the poorer natural ventilation of a long-core machine with short air-gap.

**259. Caution.** Such information as given in Figs. 118 to 121, and elsewhere in tables or curves, should be taken only as a rough guide, and as indicating the relations between the several quantities involved, rather than their absolute values. These latter may be altered over a moderate range to suit special specifications, and will vary considerably in machines

designed by different engineers to meet the same specifications. Some engineers use practically the same value of $\mathfrak{G}$ in all sizes for a given frequency.

## THE SINGLE-PHASE INDUCTION MOTOR

**260. Theory of operation.** Assume the primary current to produce a sinusoidally distributed (in space) and sinusoidally alternating (with time) *m.m.f.* This is the exact equivalent of two equal half-value sinusoidally distributed *m.m.fs.* which revolve or glide around the air gap at synchronous speed in opposite directions. This is illustrated in Fig. 122 where $\overline{00}$ is the air-gap circle, developed out into a straight line, *I* and *II* are the two oppositely revolving sinusoidally distributed *m.m.fs.*, and *A* their resultant (the alternating sinusoidally distributed *m.m.f.*). When *I* and *II* are 180 deg. apart (space phase) their resultant *A* will be zero, and then negative while *I* and *II* differ in space phase by from 180 deg. to 360 deg. Thus *I* and *II* will each have a magnitude one-half the maximum value of *A*.

**261. Comparison of revolving fields with those of three-phase motors.** It is entirely legitimate to determine the effect of the alternating *m.m.f.* upon a short-circuited secondary (*e.g.*, a squirrel-cage secondary) by superposing the effects of the two equivalent revolving *m.m.fs.* These effects may be found by the ordinary polyphase induction motor analysis.

Let *I* be the forward and *II* the backward-revolving *m.m.f.* and let $J_1$ and $J_2$ be the two equal, *m.m.f.*-equivalent, three-phase currents. Assume that the squirrel-cage rotor is revolving forward at a small slip, *s*, with respect to *I*, and therefore at a very large slip, $2-s$, with respect to *II*. The *total apparent impedance* to $J_1$ is relatively large, and that to $J_2$ relatively small, so that the e.m.f. $E_{11}$, absorbed by $J_1$, will be large as compared to the e.m.f. $E_{12}$ absorbed by $J_2$. The total impressed e.m.f. will be $E_1$, the vector sum of $E_{11}$ and $E_{12}$. $E_1$ is assumed constant. The flux of the forward-revolving field will then be much larger than that of the backward-revolving field, within the forward working range. With the rotor stationary, $E_{11}=E_{12}$, the fields are equal and produce equal and opposite torques.

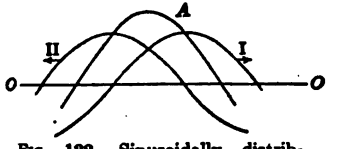

FIG. 122.—Sinusoidally distributed alternating m.m.f. resolved into two equal sinusoidally distributed oppositely revolving m.m.fs.

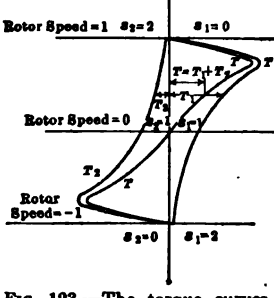

FIG. 123.—The torque curves of the two hypothetical fields of the single-phase motor, and their resultant.

**262. Speed-torque characteristics.** The torque curves of the two fields are shown approximately in Fig. 123, as $T_1$ and $T_2$, with their sum $T=T_1+T_2$. These are not normal polyphase speed-torque curves, since the impressed voltages $E_{11}$ and $E_{12}$ are not constant, each decreasing as its own slip increases.

**263. Starting torque zero.** The single-phase induction motor thus has no starting torque, but will run in either direction when once started. Near synchronism it behaves very much like a polyphase motor. The combination of the large forward field with the small backward field yields an elliptical revolving field, the major axis of which is the sum of the two fields and the minor axis of which is their difference. This elliptical field becomes an alternating or straight-line field at zero rotor speed, and a circular revolving field at synchronism.

**264. Comparison of single-phase and polyphase operation.** A Y-connected three-phase motor with one terminal disconnected from the line will constitute a fairly normal single-phase motor, see Fig. 124.

Digitized by Google

**265. Exciting current.** This is nearly twice as large as for the three-phase case, approximately half of it being the reflection in the primary of the no-load secondary current which supplies an *m.m.f.* in space and time quadrature with the primary *m.m.f.* and thus produces a revolving field.

**266. Output and rating relative to polyphase machine.** The safe single-phase rating of a three-phase motor at rated voltage is about 60 per cent. of the three-phase rating at the same voltage, but a better balance of losses is obtained at a slightly increased line voltage, when the safe output may be increased to about two-thirds that of the polyphase case.

**267. Secondary current and copper loss.** Unlike the three-phase motor, the rotor current of the single-phase motor is not zero at synchronism, but has a definite value. This may be looked upon as a part of the exciting current, and is present in lesser degree at higher slips. The secondary copper loss is also not zero at synchronism and is no longer proportional to the slip. It is obviously larger at all loads than when running three-phase.

**268. Methods of starting.** The most common method of starting single-phase induction motors is known as the split-phase method. The motor is supplied with an auxiliary winding in space quadrature with the

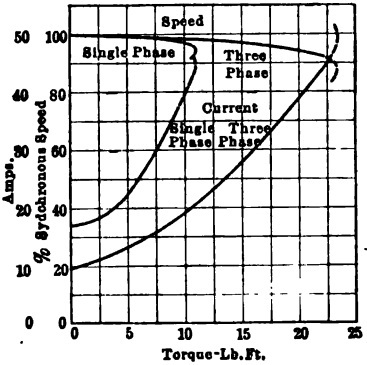

FIG. 124.—Characteristic curves of a three-phase induction motor operated (1) from a three-phase circuit and (2) from single-phase circuit.

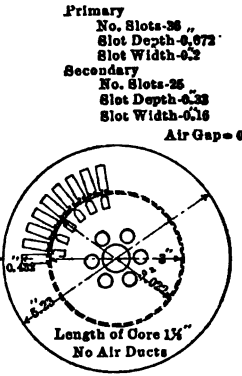

FIG. 125.—Dimensions and data of a one-eighth horsepower single-phase motor.

main windings (sometimes this consists of the third phase of a three-phase Y winding). The supply current is divided before it reaches the motor, one part going through a reactance to the main winding, and the other through a non-inductive resistance to the auxiliary or starting winding. If the resistance and reactance are properly chosen, the phase difference thus produced between the c.m.fs. $E_m$ and $E_s$ is sufficient to produce an elliptical revolving field.

Sometimes in the case of small motors which can be thrown directly on the line, $L$ is omitted and the extra resistance is obtained within the starting winding itself by using a small size of wire. In this case the cutting out of the starting winding is accomplished automatically by a centrifugal device. The dimensions and data of such a motor are given in Par. **270** and in Fig. 125. Its test data are given in Fig. 126.

**269. Design of single-phase induction motor.** From the above it is obvious that to design a single-phase motor means simply to design a good polyphase motor for about one and one-half times the desired single-phase output.

Digitized by Google

**270. Winding data for 0.125-h.p., 60-cycle, 4-pole, 110-volt, self-starting, single-phase induction motor.** See Figs. 125 and 126. The main or working winding is wound with No. 20 wire and has 1,064 active conductors. The starting winding is wound with No. 25 wire and has 576 active conductors. For each winding the active conductors are connected in series. Numbering the slots for 1 pole from 1 to 9, the following table shows the distribution of the two windings.

## SPEED CONTROL OF INDUCTION MOTORS

**271. Primary control.** The speed of an induction motor may be changed over a small range by variation of the voltage applied to the motor, the torque being proportional to the square of the voltage for any given slip. With a constant voltage supply, the voltage on the motor primary may be changed by using either series resistance or a compensator. Advantages of the primary system of control are the possibility of using the squirrel-cage rotor, and the simplicity of the resistance controller. A squirrel-cage rotor designed for this service is expensive, as its resistance must be high in order to obtain a reasonable speed variation. This results in large rotor losses, and therefore a large motor, so that the temperature may be maintained at reasonable values. Compensator control is complicated and expensive. Compensator coils cannot be short-circuited as can resistance, but must be cut out, and therefore a more complicated controller is necessary. Compensator control has a higher efficiency than resistance control, and takes less current; but it has a poorer power-factor.

**272. Secondary speed control of induction motors.** Speed variation can be obtained in an induction motor by using a wound rotor with slip-rings and connecting variable resistances between these slip-rings. By properly proportioning this rotor resistance, the starting current or the starting torque may be adjusted to any required value, and by properly designing the resistance steps, any speed-torque curve may be approximated. Fig. 127 gives four speed-torque curves where this type of control is used. Curve 1 is obtained with the slip-rings short-circuited and curves 2, 3, and 4 are

Digitized by Google

obtained with increasing resistance steps. In Fig. 128 the current-torque curve for the above speed-torque curves, is shown, the torque per amp. being independent of the speed for this type of control. Since with this method speed variation is obtained by wasting energy in rheostats, it is not suited to continuous running at speeds much below synchronous speed.

**273. Disadvantages of secondary-resistance control.** For any one value of the resistance the speed changes greatly with variations of the load and rises to practically its synchronous value at no-load, whatever be the resistance. The higher the resistance, the more the speed will vary for a small change in load. An amount of power proportional to the speed reduction is lost in the resistance, that is, if the speed is decreased to 30 per cent. below normal, 30 per cent. of the energy taken from the line is lost.

**274. Advantages of secondary-resistance control** are simplicity of connections and relatively small increase in cost of motor, over that of a constant-speed induction motor. This method is exactly equivalent to the armature-series-

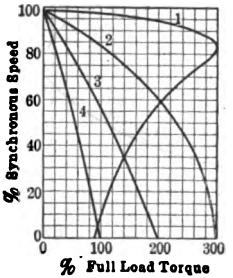

FIG. 127.—Torque speed curves of an induction motor with speed controlled by varying the resistances in series with the secondary circuits.

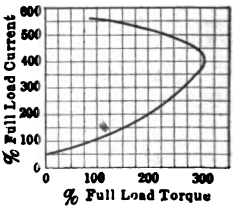

FIG. 128.—Torque-current curve for induction motor with secondary speed control.

resistance control of the speed of a direct-current shunt motor under constant voltage.

Uses—cranes, elevators and rolling mills.

**275. Frequency changing as a means of securing various speeds.** There are various ways of applying this principle and all are characterized by high first cost. *E.g.*, use several alternators of different frequencies, an objection being the trouble in throwing over from one to the other; or use alternator driven at variable speed, when each motor must have its own alternator.

**276. Speed change by variation of number of poles (multispeed motors).** It is obviously possible by regrouping the coils on the stator of an induction motor so as to alter the number of poles, to also alter the synchronous speed of the motor. With pole-changing a squirrel-cage rotor is generally used, as with a wound rotor the rotor conductors must also be regrouped. But in certain services such as in rolling mills, secondary resistance control demands a wound rotor. With an ordinary two-layer drum winding the pitch of the coils changes as the number of poles is changed: for instance a two-thirds pitch for four poles means a one and one-third pitch for 8 poles. On this account it is in practice unsatisfactory to carry the range of speed variation by pole changing beyond the 2 to 1 ratio. The above suggested pitch is on the whole the most satisfactory for a two to one change. It is quite possible to get into serious difficulties by the use of certain other pitches. This method of pole changing results in poor constants at one or both of the speeds, and the controller is usually expensive. Instead of regrouping the coils, the stator may be provided with separate windings of different pole numbers. This method is also expensive.

**277. Direct-concatenation and differential concatenation control.*** If the secondary of a wound rotor is connected to the primary of another in-

* Danielson, Ernst. "A Novel Combination of Polyphase Motors for Traction Purposes," *Trans.* A. I. E. E., Vol. XIX, page 527.

Digitized by Google

duction motor with a short-circuited secondary, and the shafts of the two motors coupled together, the two motors will run at a speed the same as that of a motor having as many poles as the two motors together. This holds if the two rotors tend to revolve in the same direction, which is called connecting the motors in direct concatenation, or direct cascade. If the motors are so connected that the rotors tend to revolve in opposite directions, the speed of the set will be that of a motor having a number of poles equal to the difference of the numbers of poles of the two motors. This connection is called differential concatenation or differential cascade.

**278. Possible speed adjustments with concatenation control.** Thus it is evident that by connecting two motors of different numbers of poles in either direct or differential concatenation, and by using either motor separately, four different speeds can be obtained. If the second machine has a wound rotor, a resistance can be used to obtain speeds between the different concatenated speeds. By providing each motor with pole-changing windings, it is obvious that the number of speeds may be great. It is rare, however, that this combination is desirable.

**279. The chief objection to cascade control** is the poor utilization of material, and the poor operating characteristics. One reason for this is that the exciting volt-amperes of the second motor must be supplied by the secondary of the first motor, and are reflected in its primary. Thus the exciting volt-amperes of the set is the sum of those of the individual motors. Another cause is that the two motors are substantially in series and their reactances add together to furnish the reactance of the set. Thus in the case of two equal motors, their combined output at breakdown will be only half that of one of them alone. In fact it will be less than half, owing to the double exciting current in the first motor. Both causes work to produce an unusually low power-factor. Finally the losses are those of two motors (although some of the losses are less than when the motors are running alone at full-load) with a combined output about one-half that of a single motor. The efficiency is thus very low.

**280. Actual operating data of cascade control.** These points are illustrated by the curves of Figs. 129 and 130 taken from actual tests: the

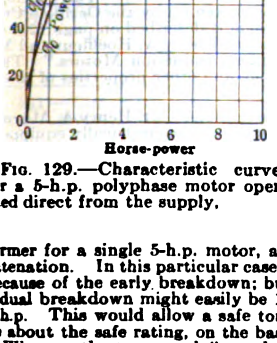

FIG. 129.—Characteristic curves for a 5-h.p. polyphase motor operated direct from the supply.

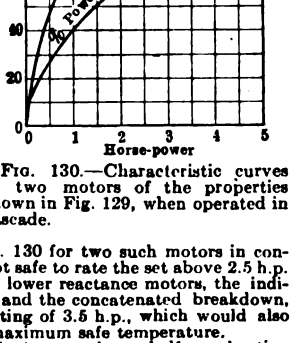

FIG. 130.—Characteristic curves of two motors of the properties shown in Fig. 129, when operated in cascade.

former for a single 5-h.p. motor, and Fig. 130 for two such motors in concatenation. In this particular case it is not safe to rate the set above 2.5 h.p. because of the early breakdown; but with lower reactance motors, the individual breakdown might easily be 13 h.p. and the concatenated breakdown, 6 h.p. This would allow a safe torque-rating of 3.5 h.p., which would also be about the safe rating, on the basis of maximum safe temperature.

Whereas the two-speed (by pole changing) motor has a half-speed rating of more than half of its full-speed rating, the concatenated rating of two equal motors is at most only about one-third of the combined full-speed

Digitized by Google

rating. If, however, a 16 h.p. 16-pole motor be concatenated with a 4-h.p. 4-pole motor, their combined synchronous speed at 60 cycles will be 360 rev. per min. Neglecting losses, four-fifths of the electrical power delivered to the 16-pole motor will be converted to mechanical power and one-fifth transmitted to the 4-pole motor and there converted into mechanical power. In this case, the breakdown output of the set will be a little less than four-fifths that of the large motor, which is not a sufficient reduction to influence the rating of the set, which on a heating basis will be only a little less than that of the larger motor, or a little less than four-fifths that of the two motors combined. The same is true of the differential concatenation with a speed of 600 rev. per min. This set thus has three speeds—360, 450, 600 (rev. per min.), all with approximately the same power, and a speed of 1,800 rev. per min. with the small motor alone, but at only 4 h.p. In differential cascade the small machine acts as an induction generator and frequency changer. This arrangement will not start itself except by connecting the small motor to the line until the speed is nearly that desired, then throwing over to the differential cascade connection. The cascade operation is thus much more economical and efficient for moderate speed changes, while the pole changing method is more satisfactory for a two- to one-speed ratio.

**281. The spinner motor.** Different speeds are secured with the spinner motor by a combination of electrical and mechanical features. The motor consists of a "stator" or fixed primary, a "rotor," and between them a "spinner" rotating independently of the rotor, and having a short-circuited winding which is the secondary for the stator, and a slip-ring winding which is the primary to the rotor. The primary on the stator and that on the spinner are wound for different numbers of poles, the stator being usually wound for the larger number of poles, owing to the larger diameter.

**282. Securing various speeds with spinner motor.** By clutching together the spinner and rotor, and exciting only the stator winding, one speed is obtained; by exciting only the spinner and locking it to the stator, a second speed of the rotor is obtained; by allowing the spinner to run free and exciting both winding so that the *m.m.f.* of each travels in the same direction, gives a third speed, the sum of the two elementary speeds, and by exciting them so that the *m.m.f.* travels around them in opposite directions gives a fourth speed, the difference between the two elementary speeds.

**283. Bibliography of spinner motor.** The development of the spinner motor is due Mr. Henry A. Mavor, who has described it in the following papers: "Electric Propulsion of Ships" read before the Institute of Engineers and Shipbuilders in Scotland, on Feb. 18, 1908; and "Marine Propulsion by Electric Motors," read at the Institute of Civil Engineers, on Dec. 7, 1909 (see p. 134 of Vol. CLXXIX of *Proc.* I. C. E.). The development of this type of motor has recently been taken up by the Oerliken Co., and a line of spinner motors developed by them is described on page 1247 of the Electrical World for May 30, 1914, in an article by A. Hoeffleur and M. P. Misslin entitled "Adjustable-speed Polyphase Induction Motors." The article contains complete data of the efficiency and other properties of these motors at various speeds.

**284. Multiple motor.** This is also the invention of Mr. Henry A. Mavor. A 500-h.p. motor of this type has been employed on the electrically equipped cargo boat Tynemount (Sec. 18). The rotor is of the squirrel-cage type. The stator has two independent mutually non-inductive windings of different pole numbers. For full-speed and power these two windings are fed with electricity of frequencies proportional to their pole numbers and hence cooperate to drive the rotor at a given speed. For low speed and power, the winding of greater pole-number is fed from the supply of lower frequency and drives the motor at the corresponding low speed. The motor is described in British Patent, No. 12917, of 1909.

**285. The "Hunt" internally concatenated motor.*** This machine operates upon the "cascade" principle, having two superimposed magnetic systems in the stator, one field being generated by the stator winding, and the second by the rotor winding which reacts upon the stator producing the second magnetic field and giving the cascade effect. Consider the case of a

* Hunt. *Journ.* I. E. E.; Vol. LII, 1913, p. 406.

Digitized by Google

motor wound for a 12-pole cascade speed. The stator is provided with an ordinary 8-pole winding, divided into sections which are connected in parallel. The rotor is wound in such a way that either an 8-pole or both an 8-pole and a 4-pole winding can be obtained by either short-circuiting or open circuiting the rotor slip-rings, producing either an 8-pole or a 12-pole speed of the motor. The starting rheostat is connected across the rotor slip-rings. The Hunt motor gives constant torque at the different speeds, the output being therefore proportional to the speed.

## ALTERNATING-CURRENT COMMUTATOR MOTORS

**286. Classification.** Alternating-current commutator motors may be grouped into two classes, as follows:

(a) Those motors in which the resultant *m.m.f.* providing the flux, increases with the load. When operated from a source of constant pressure, the speed of such motors decreases with increasing load. They are termed series motors from the similarity of their characteristics to those of series-wound direct-current motors, (b) those motors in which the resultant *m.m.f.* providing the flux, is substantially constant irrespective of the load. For operation from a source of constant pressure, the speed of such motors is approximately constant. The speed may, however, be increased or decreased (independently of the load) by increasing or decreasing the pressure at the terminals of the motor, or by the provision of suitably disposed and connected auxiliary coils. Such motors are termed shunt motors.

Alternating-current commutator motors are either single phase or polyphase.

**287. Single-phase straight series.** An ordinary direct-current series motor if constructed with a well-laminated field circuit, will operate (although unsatisfactorily) if connected to a suitable source of single-phase alternating electricity. Since the armature is in series with the field, the periodic reversals of current in the armature will correspond with simultaneous reversals in the direction of the flux, and consequently the torque will always be in the same direction. But the inductance of the motor will be so great that the current will lag greatly behind the voltage, and the motor will have a hopelessly poor power-factor. Such a motor is shown diagrammatically in Fig. 131, in which *F* represents the field and *A* the armature.

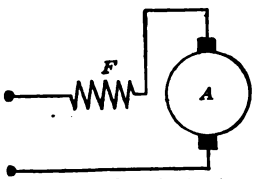

FIG. 131.—Circuit of series motor.

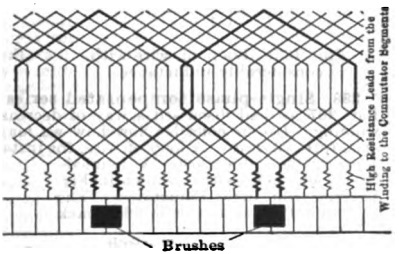

FIG. 132.—Diagram showing location of high-resistance leads between the winding and the commutator segments.

When the motor is first thrown on the circuit and before the armature has moved from rest, the field constitutes the primary of a transformer and sends flux through the armature core. Those armature turns which at that instant are short-circuited under the brushes, act as short-circuited secondary coils and are traversed by heavy currents which serve no useful purpose whatsoever and occasion serious heating. As soon, however, as the armature starts to revolve, these short-circuited turns are opened as they pass out from under the brushes and they are replaced by other turns which are momentarily short-circuited and then opened. These interruptions of heavy currents are accompanied by serious sparking since the heating is concentrated at the few segments on which the brushes rest. As soon, however, as a certain speed is acquired, the heating is distributed over all the segments and the conditions become ameliorated. This source of sparking is, then, most serious

Digitized by Google

at the moment of starting. One way in which it has often been sought to decrease this difficulty, has been by the employment of leads of high resistance connecting the winding to the commutator segments as indicated in Fig. 132. The extra-heavy lines in this diagram indicate the coils which, at the particular instant considered, are short-circuited under the brushes. This practice of introducing resistance leads between the winding and the commutator segments has often been carried so far that notwithstanding the brief time during which each lead is in circuit, the loss in the leads has been sufficient to decrease seriously the efficiency, and to constitute a considerable component in the total heating of the motor. Obviously, however, the method affords a means of limiting the short-circuit currents occasioned by transformer action, and consequently improves the commutation during starting.

The alternating current in the intermediate conductors (shown in lighter lines in Fig. 132) is always in such directions relatively to the alternating magnetic flux set up by the field winding, as to occasion in the conductors a torque in a constant direction. The motor consequently has the necessary properties and it becomes of interest to investigate means for overcoming its faults. How can the power-factor of the motor be improved; how can we decrease its inductance? We can reduce the inductance of the field winding by employing few turns. This requires designing the magnetic circuit for low magnetic densities (which, in turn, tends to make the motor large and heavy), and with small air gaps.

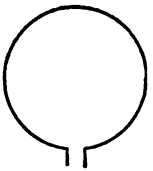

FIG. 133.—Loop of wire with considerable inductance.

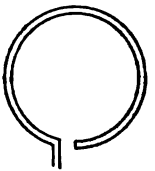

FIG. 134.—Doubled-back loop with negligible inductance.

**288. Single-phase compensated series motor.** At the conclusion of Par. **287** we had discussed a way of decreasing the inductance of the field winding. Let us consider now how we may reduce the inductance of the armature winding. A loop of wire, for instance that shown in Fig. 133 has considerable inductance. A doubled-back loop such as that shown in Fig. 134 has but little inductance. The current returning in the doubled-back loop neutralizes the effect of the outgoing current in the first loop. Such a winding is practically non-inductive.

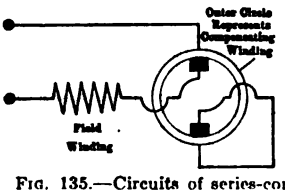

FIG. 135.—Circuits of series-compensated motor. [The inner circle represents the rotor winding and the outer circle represents the compensating winding, which is on the stator.]

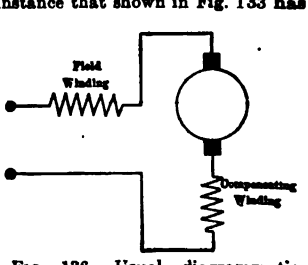

FIG. 136.—Usual diagrammatic representation of a series-compensated motor.

We may crudely imitate this in a motor. If the current after flowing through all the turns of the armature winding is compelled to flow in the re-

Digitized by Google

verse direction through a winding of just the same number of turns arranged in as close proximity as possible to the armature winding, then the magnetomotive force of the second (or compensating winding) balances the magnetomotive force of the armature winding, that is to say, it renders it non-inductive. Unfortunately in applying this principle to our single-phase motor, we are constrained to locate the compensating winding on the stator, *i.e.*, on the side of the air gap remote from the armature winding. Consequently, we fall considerably short of rendering the system *completely* non-inductive; nevertheless, it is by means of this plan that single-phase motors are made commercially effective. In order to obtain the best results, the compensating winding should be distributed around the stator surface similarly or equivalently to the manner in which the armature winding is distributed around the rotor surface. It does not suffice to have the same *total* *m.m.f.* in each, but it is important that, *at each part* of the periphery, the neutralisation shall be as complete as practicable. The arrangement may be indicated as shown in Fig. 135, in which the outer circle represents the compensating winding. For diagrammatic purposes, however, it is more usual to replace the outer circle by a coil whose axis is in the direction of the *m.m.f.* set up in the compensating winding when the current flows through it. Whereas the main field coil is in space-quadrature with the *m.m.f.* of the armature winding, the *m.m.f.* of the compensating winding is in the same space phase as the armature *m.m.f.*, but in the opposite direction. In Fig. 136 the compensating winding is represented diagrammatically by a coil with its axis coinciding with the brush axis. That this is the required location may be more clear if attention is drawn to the fact that the armature winding, considered by itself, constitutes a source of *m.m.f.* whose direction is in a line through the brushes. Whatever the actual form adopted for the armature winding, it is at any instant equivalent to the winding shown in Fig. 137 as far as relates to its *m.m.f.* Assembling around the armature, the field coil and the compensating coil in their appropriate angular positions, as in Fig. 138, we obtain an instructive diagrammatic representation of a single-phase compensated series motor.

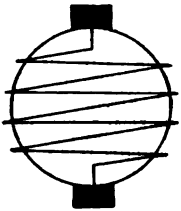

FIG. 137.—"Equivalent" armature winding.

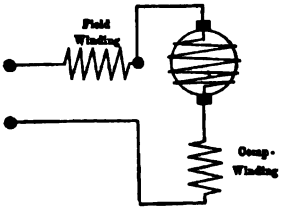

FIG. 138.—Diagram of a series-compensated motor indicating that the compensating winding lies in the same axis as the "equivalent" armature winding, and opposes it.

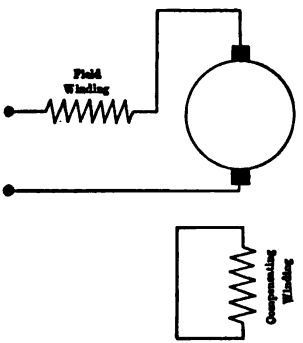

FIG. 139.—Inductively compensated series motor.

**289. Inductive and conductive compensation.** Compensation may be "conductive," as shown in Figs. 135, 136, and 138, or it may be "inductive"

Digitized by Google

as shown in Fig. 139. With the latter arrangement the compensating currents are induced in the short-circuited compensating coil just as current is induced in the short-circuited secondary of a transformer. And similarly to the case of the transformer, the secondary current automatically rises to such a value as to occasion a *m.m.f.* approximately equal and opposite to the primary *m.m.f.* But "conductive" compensation is preferable, for it permits of control and adjustment of the compensating *m.m.f.* Under some circumstances it is desirable to be able to *over*compensate, *i.e.*, to set up in the compensating coil a *m.m.f.* which shall slightly exceed the armature *m.m.f.* This is readily effected with "conductive" compensation, but not with "inductive" compensation.

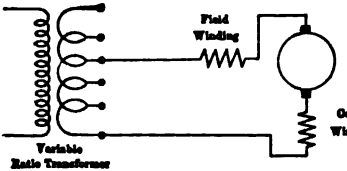

FIG. 140.—Series-compensated motor supplied from a variable-ratio transformer.

**290. Speed control.** Fairly good single-phase motors have been constructed on the principles which have been set forth in Par. **288** and **289**. Such motors have series characteristics, their speed decreasing as their load increases. This must obviously be the case, for the field excitation is occasioned by the flow of the armature current through the field winding. Thus the flux increases with the load and the armature will decrease in speed since the counter e.m.f. must, as in a direct-current motor, be slightly less than the terminal voltage. But, while for a given terminal voltage, the speed decreases with increasing load; nevertheless we can readily arrange that such a motor shall, for any load, be operated at any desired speed over quite a wide range. This is done by supplying the motor from taps out of a transformer across the main circuit. The arrangement is shown diagrammatically in Fig. 140. By varying the position at which the adjustable terminal of the motor is tapped into the secondary of the transformer, we can vary the voltage impressed on the motor and thus readily control and adjust its speed. An alternating-current series motor has in this respect an important advantage over a direct-current series motor, since in the latter the speed control can

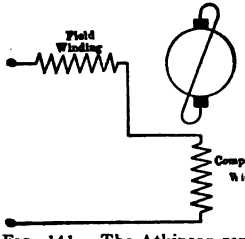

FIG. 141.—The Atkinson repulsion motor.

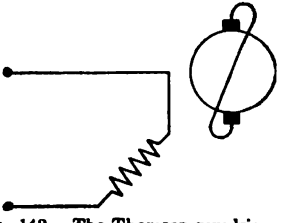

FIG. 142.—The Thomson repulsion motor.

be effected simply only by varying the amount of resistance in series with the motor, and consequently with a serious loss in efficiency.

**291. Single-phase repulsion motor.** It is only a step from the inductively compensated motor illustrated in Fig. 139 to a motor in which current is induced in the armature circuits by means of the *m.m.f.* set up in the compensating winding when current is sent through it. The motor at which we thus arrive is shown diagrammatically in Fig. 141. Instead of short-circuiting the compensating winding, we short-circuit the armature winding. In other words we simply exchange the relations of compensating winding and armature winding which were shown in Fig. 139.

Digitized by Google

**292. Evolution of the repulsion motor.** The connection shown in Fig. 141 is known as the **Atkinson repulsion motor.** It was suggested by Atkinson many years after the invention by Prof. Elihu Thomson of the *simple* repulsion motor. In the original **Thomson repulsion motor** the field coil and the compensating coil shown in Fig. 141 find their equivalent in a single coil which may be looked upon as supplying a *m.m.f.* of which the field *m.m.f.* and the compensating *m.m.f.* in Fig. 141 are the components. The Thomson repulsion motor is shown in Fig. 142. The stator coil has, in this figure, been drawn in a position intermediate between the positions of the compensating coil and the field coil in Fig. 141 in order to emphasize the idea that these two component coils have been replaced in magnitude and direction by their resultant. As must be evident from the nature of its evolution, the Thomson repulsion motor also has the characteristic of a series motor in that its speed decreases with increasing load.

**293. Single-phase compensated repulsion motor.** Many pioneers in the design of direct-current motors have long ago sought to bring the field coil close down around the armature in order to obtain the full effect of the field *m.m.f.* right at the armature where it is desired. Eickemeyer's name is closely associated with designs of this sort. What could more closely approximate to the desired result than to employ the armature winding itself as the locus for the excitation? Several inventors conceived this idea practically simultaneously. They accomplished their purpose by applying to the

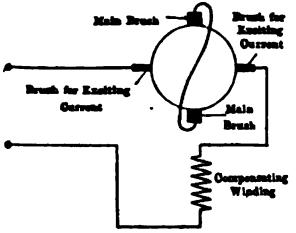

FIG. 143.—Compensated repulsion motor. [Latour-Winter-Eichberg.]

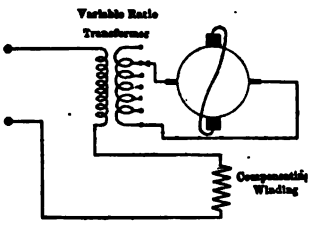

FIG. 144.—Compensated repulsion motor supplied from a variable-ratio transformer.

commutator a second set of brushes situated in quadrature with the main brushes and sending the exciting current through the armature winding by means of these additional brushes as shown in Fig. 143, which should be contrasted with the Atkinson repulsion motor of Fig. 141. It will be seen that the field coil has been eliminated from the stator circuit, and that its function has been assumed by the armature winding through which the current is carried by means of the two auxiliary brushes. The arrangement shown in Fig. 143 is termed a compensated repulsion motor. This motor also has a series characteristic.

It would seldom or never be convenient to wind the armature of Fig. 143 with the particular number of turns which is suitable for the field excitation. Consequently it becomes necessary to supply the excitation from the secondary of a transformer whose primary is in series with the compensating winding. This arrangement, which is shown in Fig. 144, has the further useful feature of permitting speed control by varying the point at which the field excitation circuit is tapped off from the secondary of the transformer. The compensated repulsion motor illustrated in the above two figures was independently invented by Latour in France and by Winter and Eichberg in Germany. It would be futile to undertake here an enumeration of the dozens of variations in the above fundamental types of single-phase commutator motors with a series characteristic.

**294. Polyphase commutator motors with a series characteristic.** In Fig. 145 is shown the simplest form of **Görges three-phase motor.** Its rotor has an ordinary direct-current winding with a commutator on

Digitized by Google

which rest three equidistant brushes per pair of poles. The diagram indicates a bipolar motor. The brushes are connected to the terminals of the three stator windings, which, in turn, are supplied either directly from the line, or else, as indicated in the diagram, from the secondary of a step-down transformer. Usually the most suitable voltage for the stator windings will be higher than that most suitable for the commutator. Consequently, the arrangement shown in Fig. 146 is often to be preferred. This latter arrangement permits of employing, for the rotor, the low voltage which is essential to obtaining good commutation. Such motors have a series characteristic; that is to say, the speed decreases as the load increases.

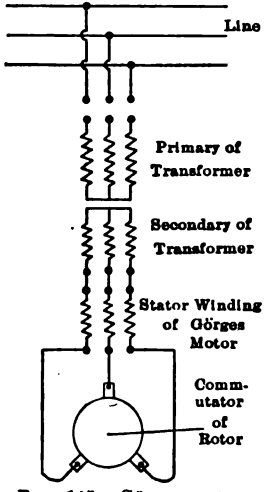

FIG. 145.—Görges motor with transformer between line and stator windings.

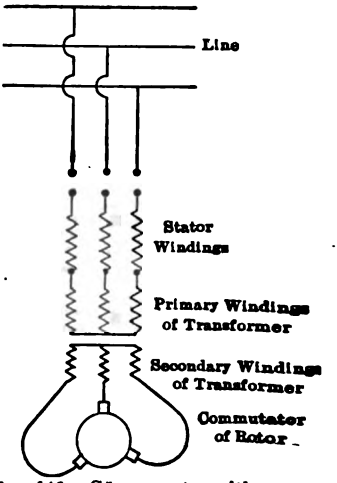

FIG. 146.—Görges motor with transformer between stator and rotor.

**295. Variable-speed polyphase commutator motors.** The speed can be adjusted, for any load, by shifting the brushes through an appropriate angular distance, maintaining the 120-deg. relation between the three brushes. This is done in the General Electric Co.'s brush-shifting type of variable-speed polyphase motors.

**296. Compensation of polyphase commutator motors with series characteristics.** For the reasons already discussed in connection with the compensation of single-phase commutator motors, it is of advantage in polyphase commutator motors to fit them with compensating windings at right angles to the exciting windings. The cost, however, is necessarily increased, and in America the use of compensating windings is not customary for such motors. The arrangement, when compensating windings are employed, is indicated diagrammatically in Fig. 147, in which the three exciting windings $a^1b^1c^1$ on the stator are supplied from the three lines *abc*. After passing through the three exciting windings the current passes through the compensating windings *def* which are located with their magnetic axes in line with the magnetic axes of the rotor brushes. The addition of these compensating windings improves the power-factor and permits of obtaining better commutation. Since the most suitable voltage for the main field windings on the stator will often be different from that most suitable for the commutator, and for the compensating windings on the stator, it would be preferable to employ in place of the arrangement indicated in Fig. 147a modified arrange-

Digitized by Google

ment in which the main field windings are located between the supply circuit and the primary windings of the transformer, while the compensating and rotor windings, connected in series, are supplied from the secondary of the transformer.

**297. Single-phase commutator motors with a shunt characteristic for operation at a single speed.** The only object in employing a commutator in the construction of a single-phase motor to operate at but one constant speed, is to provide control of the power-factor. Otherwise the single-phase induction motor with a squirrel-cage rotor would be preferable. The Atkinson commutator induction motor indicated diagrammatically in Fig. 148 is the forerunner of all single-phase commutator motors with shunt characteristics. It consists of a stator with a distributed winding, and a rotor fitted with a commutator and with two sets of short-circuited brushes $xx$ and $yy$. There is no torque when the motor is at rest. If, however, the motor is started in either direction, interactions occur which occasion in the $xx$ axis a current in phase with the line voltage applied to the stator. This current sets up a flux along the $xx$ axis. As the rotor acquires speed, the current induced in the $yy$ axis by the stator winding, comes more nearly into phase with the flux in the $xx$ axis and consequently the torque increases. In this motor the torque increases in proportion to the speed, from the zero value corresponding to standstill. When the speed of the rotor nears synchronism, the motor is equivalent to a squirrel-cage induction motor, except that in place of having end-rings effecting a good simultaneous short-circuit of all the rotor conductors, there are only two short-circuiting connections by means of the two pairs of brushes. Obviously there is no feature in this *elementary*

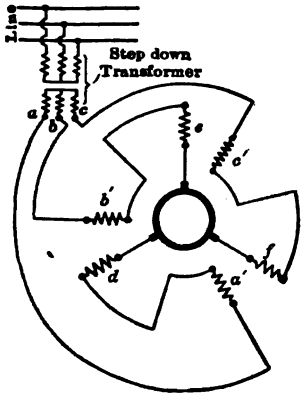

FIG. 147.—Compensated Görges motor.

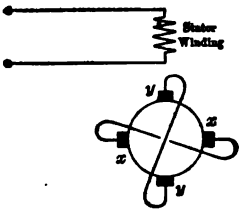

FIG. 148.—Atkinson commutator induction motor.

commutator motor which will improve the power-factor as compared with that of the single-phase squirrel-cage induction motor.

**298. Compensation of single-phase commutator motors with shunt characteristics.** Various inventors have indicated methods of "compensating" such a motor, *i.e.*, of improving its power-factor. These methods resolve themselves into the following classification: (a) introducing in the circuit of the $yy$ brushes a stator winding in the $xx$ axis; (b) introducing in the circuit of the $xx$ brushes a stator winding in the $yy$ axis; (c) introducing in the circuit of the $xx$ brushes an e.m.f. in phase with the line pressure. These three methods are shown in Figs. 149, 150, and 151.

**299. Single-phase commutator motors with a shunt characteristic and an adjustable speed.** There is quite a demand for single-phase commutator motors with a shunt characteristic and with means for adjusting the speed. For any particular adjustment the speed will be substantially constant at all loads. The usual methods for accomplishing this are based upon the investigations of Punga, Fynn, Creedy and Milch. The simplest method consists in introducing in the $yy$ axis an electromotive force of the same phase as the line pressure. This may be done by means of a transformer as shown in Fig. 152. If the secondary coil $A$ in the above figure provides a

Digitized by Google

*m.m.f.* acting in the same direction as the coil *B*, the speed of the motor will be increased. If *A* is connected to oppose *B*, the speed of the motor will be decreased. Speed control may also be obtained by introducing into the

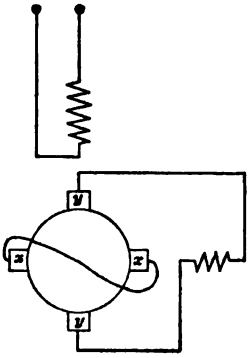

FIG. 149.—Single-phase commutator motor with *power-factor*-modifying coil supplied from the *yy* brushes.

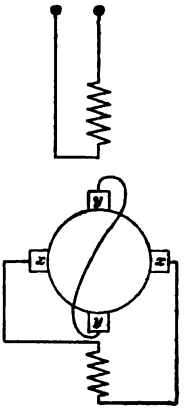

FIG. 150.—Single-phase commutator motor with *power-factor*-modifying coil supplied from the *xx* brushes.

circuit of the *xx* brushes a stator winding *A* located in the *xx* axis as shown in Fig. 153. Connecting *A* in the one direction increases the speed: connecting it in the other direction decreases the speed. Still another method of obtaining speed control is shown in Fig. 154 and is the invention of Creedy. In this case the field along the *xx* axis is weakened or strengthened and the speed varied, by varying the amount of inductance or capacity in the circuit of the *xx* brushes.

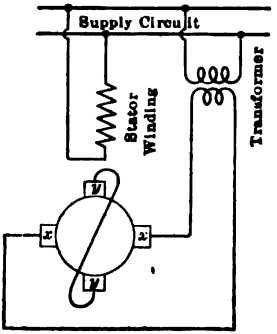

FIG. 151.—Single-phase commutator motor with *power-factor* modified by an e.m.f. interpolated in the *xx* axis by means of a transformer supplied from the line.

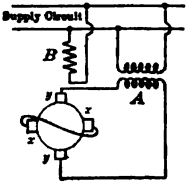

FIG. 152.—Single-phase commutator motor with *speed* modification by means of an e.m.f. interpolated into the *yy* axis by means of a transformer supplied from the line.

**300. Single-phase repulsion-starting induction motor (Arnold motor).** This motor which is built under the patent of the late Prof. E. Arnold of Karlsruhe, in Germany, is extensively used in the United States.

Digitized by Google

The connections at starting are those for a repulsion motor as shown in Fig. 142, the brush axis standing at an angle with the axis of the stator winding and the brushes being short-circuited. This connection permits of starting with high torque. When a certain speed is attained, a centrifugal governor acts to short-circuit all the commutator segments and to remove the brushes from the commutator. The motor then operates just like a squirrel-cage

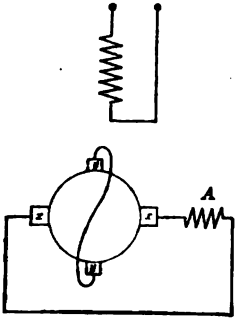

FIG. 153.—Single-phase commutator motor with speed modification by means of a coil fed from the $xx$ brushes and located on the stator in the $xx$ axis.

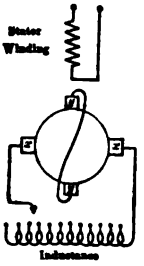

FIG. 154.—Creedy single-phase commutator motor with speed variation by inductance in the $xx$ circuit.

induction motor and maintains approximately constant speed at all loads. It is usually preferable to employ starting boxes in sizes above 7.5 h.p., but smaller sizes are usually thrown directly on the line. The motors develop a starting torque (when thrown directly on the line) of some 250 per cent. of full-load torque, consuming approximately 250 per cent. of full-load current. (See Fig. 155.)

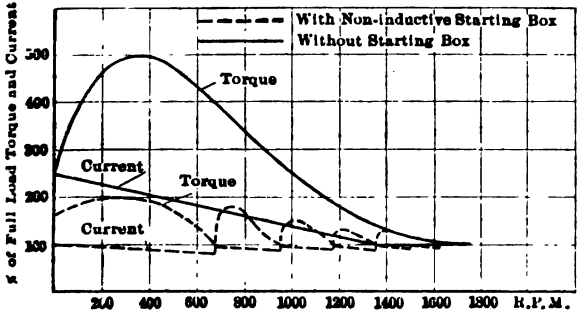

FIG. 155.—Starting characteristics of Arnold single-phase commutator motor. (Taken from the manufacturer's publications.)

**301. Motor with repulsion starting, gradually converted into "induction" operation. (Schüler motor.)** This type was developed by Schüler for the Ferranti Co. in England. It started as a repulsion motor and was gradually converted into a single-phase induction motor by the gradual decrease in resistances connected to slip-rings. These resistances

Digitized by Google

are great at starting and are reduced to zero at full speed. This sequence o operations results in giving the motor excellent characteristics. The Schüle motor is described on pp. 712 to 720 of the 2nd edition of Hobart's "Elec tric Motors."

**302. The Wagner "Unity Power-factor" Type BK motor.** In 191 the Wagner Electric Co. placed upon the market a constant speed single phase commutator motor so constructed as to provide a leading power-facto at no-load and at light loads, and unity power-factor at rated load. Th arrangement is represented diagrammatically in Fig. 156. As indicated in this diagra there are two stator windings 1 and 2. Dur ing starting, the switch (9) is open, so tha only the stator winding (1) is in circuit. Th motor consequently starts up with good torqu

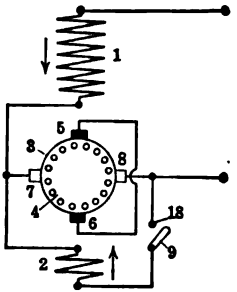

FIG. 156.—Diagrammatic representation of the Wagner "Unity-Power-Factor" (Type BK) motor. 1.—Initial field magnetization winding. 2.—Auxiliary winding which controls the power-factor or compensates the motor.

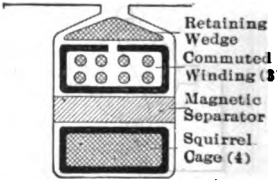

FIG. 157.—Diagrammatic rep resentation of design of rotor slo of Wagner "Unity-Power-Factor" (Type BK) motor.

as a series motor. The rotor slot design is shown in Fig. 157. During start ing, the squirrel-cage winding (4) is more or less inert as it is protected by th magnetic separator shown in Fig. 157. The magnetic separator is describe in the manufacturer's publications as consisting of a rolled-steel bar. Th upper winding (3) is termed a "commuted" winding. It is connected to commutator in the manner usual in direct-current motor armatures. A speed is acquired, the activity of the squirrel cage increases, and it contrib utes a torque which increases very rapidly as synchronism is approached

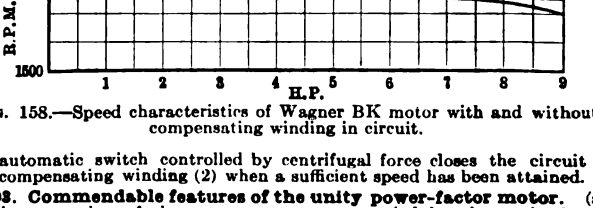

FIG. 158.—Speed characteristics of Wagner BK motor with and without compensating winding in circuit.

An automatic switch controlled by centrifugal force closes the circuit of the compensating winding (2) when a sufficient speed has been attained.

**303. Commendable features of the unity power-factor motor.** (a) "A large portion of the rotor currents are carried by the squirrel-cage winding, in normal operation, thus imposing light-load service on the commutator." (b) "The close proximity of the squirrel-cage to the commuted winding suppresses to a large extent the short-circuit currents which tend to flow in the individual coils of the commuted winding as they pass under the brushes. This again very greatly lightens the commutator service."

Digitized by Google

(c) "The employment of the squirrel cage secures a remarkably constant speed at all loads." This is indicated in Fig. 158 in which are plotted speed curves for the compensating circuit open and closed. (d) "The squirrel cage absolutely prevents the unity power-factor motor from running away or racing. No possible accident to the commutator, brush gear or automatic switches of this motor can cause the speed variations between no-load and full-load to exceed 4 per cent. When the compensating circuit (which includes the winding 2 of Fig. 156) is closed, the speed variation is shown by the least sloping curve of Fig. 158 and does not exceed 1.5 per cent. Should the compensating circuit be entirely interrupted, then the speed variation will not increase to more than 4 per cent., as indicated by the more sloping curve of Fig. 158."

**304. The General Electric Co.'s RI (repulsion-induction) motor.** Diagrammatically the General Electric Co.'s single-phase commutator motor of the RI type may be represented by Fig. 159. Leaving out of consideration the compensating brushes and winding, the motor is seen to be a Thomson repulsion motor (see Par. 292). Such a motor would, however, have two faults. In the first place, it would have a low power-factor, and in the second place its speed would vary greatly with varying loads. The addition of the compensating winding improves the power-factor and also decreases the amount of the variation of the speed with the load. The motor is not designed for constant speed but for such a moderate decrease in speed

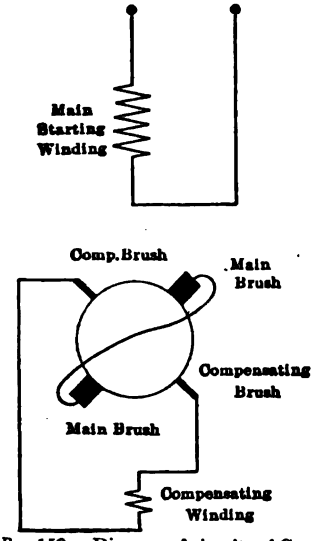

FIG. 159.—Diagram of circuits of General Electric Co., Type RI motor with independent compensating circuit.

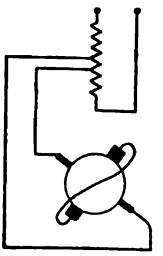

FIG. 160.—Diagram of RI motor with compensation by tapping the main stator winding.

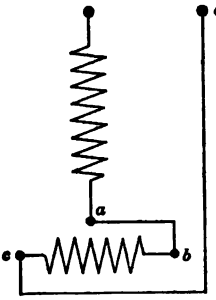
with increasing load as is considered desirable in a compound-wound continuous-electricity motor. An RI motor may be started by simply closing the line circuit of the motor. It will have a starting torque of 200 to 250 per cent. of full-load torque. If it is desired to reduce the starting current, a resistance box with low-voltage release may be used. This is proportioned to give 150 per cent. of full-load current on the first step. These motors are built for 25, 40 and 60 cycles and for synchronous speeds (at 60 cycles) of 1,200 and 1,800 rev. per min.

**305. Compensation.** In some of the smaller sizes the compensation is obtained by taps from the main winding instead of from a separate winding as shown in Fig. 159. The tapped arrangement is indicated diagrammatically in Fig. 160.

**306. In reversible repulsion-induction motors (Par. 304)** an auxiliary winding in space-quadrature with the main winding is provided. This

Digitized by Google

winding is connected in the one or the other direction with respect to the main winding according to the direction of rotation desired. The scheme is indicated diagrammatically in Fig. 161. To reverse the direction of rotation, *a* would be connected to *c*, and *b* would be connected to *d*. It is to be observed that in Fig. 161, the axis of the main brushes coincides with the axis of the main stator winding but has the same angle to the resultant of the main and reversing stator windings, which, in Fig. 159, it had with the main stator winding. Were no reversing winding provided, then in order to reverse the direction of rotation it would be necessary to shift the brushes over to the corresponding angle on the other side from the position for normal direction of rotation.



**307. Repulsion-induction motors may be fitted for adjustable-speed operation** (Par. **299**) by employing a transformer with its primary excited from the line circuit and its secondary interpolated in the circuit of the energy brushes. Such motors are arranged for a speed range of about 2 : 1, approximately one-half of this range being below and one-half above synchronous speed. Finally,

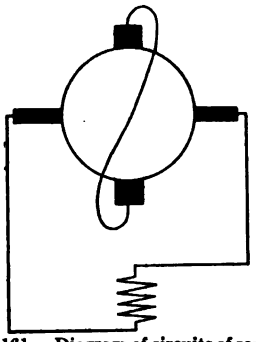


FIG. 161.—Diagram of circuits of reversible RI motor (General Electric Co.).

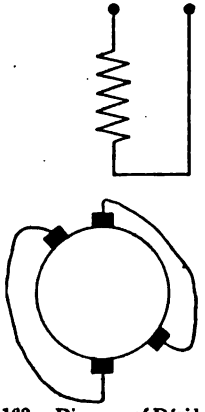

FIG. 162.—Diagram of Déri brush-shifting motor.

*RI* motors are also arranged to give variable speed by shifting the brushes. A speed variation of 2 : 1 is provided in this way.

**308. The Déri single-phase motor with speed control by brush shifting.** Fig. 162 is a diagrammatic representation of the Déri single-phase motor. In this motor the speed is varied by varying the position of the brushes. Two of the brushes (those lying in the axis of the stator winding) are of fixed position. The other two are mounted on a movable yoke. For any given brush position the speed decreases with increasing load. Thus the motor has a series characteristic. The motor has good starting torque, the maximum value occurring when the movable brushes are at an angle of some 150 deg. to 160 deg. from the fixed brushes.

The motor is widely employed abroad for driving textile machinery. The simple mechanical arrangements required to effect the shifting of the brushes are less expensive than equivalent control devices which permit of

Digitized by Google

accomplishing the speed variations without brush movement. Schnetzler has described the Déri motor in a paper published in the E. T. Z. for Nov. 14 and 21, 1907 at pp. 1097 and 1128. There is also a description of the Déri motor occupying pages 669 to 685 of the 2nd Edition of Hobart's "Electric Motors."

**309. The Punga-Creedy single-phase commutator motor.** Adjustable-speed, single-phase, commutator motors built under the Punga-Creedy patents have been placed on the British market by Messrs. F. Parkinson & Co., of Leeds. The motor is started by being thrown directly on the line and yields a starting torque of twice full-load torque, consuming twice full-load current. Figs. 163, 164 and 165 show (1) the speed-torque, (2) efficiency, and (3) power-factor curves for a 6-h.p. Punga-Creedy motor for printing-press work. Allusion has already been made in Par. 220 to the principles employed in motors of this class. The chief patents employed in the Punga-Creedy system are Punga's British Patent No. 10585 of 1906 and Creedy's British Patent No. 5136 of 1906. Punga and Creedy tested motors embodying these principles at early dates. The results of a number of these tests have been published in the *Trans.* A. I. E. E., Vol. XXVIII (1909), p. 475, in a paper by Creedy entitled "A sketch of the theory of adjustable-speed, single-phase commutator motors."

**310. Polyphase shunt commutator motors.** The most usual arrangement of a polyphase shunt commutator motor is that known as the **Winter-Eichberg type.** It is shown diagrammatically in Fig. 166 and is seen to consist of a motor with a three-phase stator and a commutator rotor. The speed will depend upon the pressure applied to the commutator brushes. By using a

variable-ratio transformer as indicated in the diagram, the speed will be greater, the smaller the secondary voltage applied to the brushes. Such motors have not come into extensive use. They are large and expensive for their output and the cost for the variable-ratio transformer is a serious consideration. The whole equipment will cost over twice as much as an equivalent continuous-current equipment.

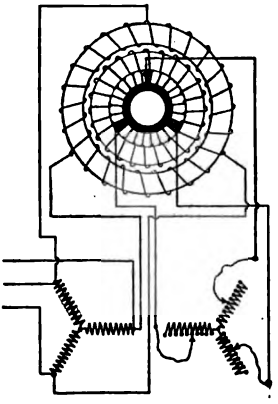

FIG. 166.—Diagrammatic representation of Winter-Eichberg type of polyphase shunt commutator motor.

**311. Quarter-phase shunt commutator motor with adjustable speed by field control.** In Fig. 167 is shown a type of motor in which the compensating winding and the armature winding are fed from one phase of a quarterphase system while the exciting winding is fed from the other phase. Since the compensating and armature winding constitute a circuit of low inductance, the current in this circuit is practically in phase with the pressure of the circuit from which they are supplied. But the exciting circuit is highly inductive and its current lags practically 90 deg. behind the pressure of the circuit to which it is connected and 180 deg. behind the current in the armature. The armature current and the magnetic flux are consequently in phase, just as in a simple single-phase series motor. The motor is thus the equivalent of a direct-current motor with shunt excitation. Its speed for any given field strength is practically constant at all loads. But any desired speed can be obtained by inserting reactance of suitable amount in series with the excitation winding. Speed control can also be obtained by supplying the main circuit from a variable-ratio transformer. On page 2488 of Part III of Vol. XXX (1911) of the *Trans.* A. I. E. E., Mr. B. G. Lamme discusses this type of motor and alludes to a 20-h.p., 25-cycle motor built in this way which gave excellent satisfaction and with which the speed was adjustable from practically zero up to 1,000 rev. per min. The speed was controlled by adjustable armature pressure from transformers.

Mr. Lamme also mentions the equivalent arrangement shown in Fig. 168. In this arrangement the armature circuit instead of being conductively

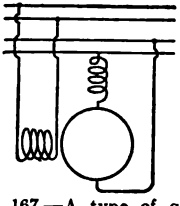

FIG. 167.—A type of quarter-phase, variable-speed commutator motor.

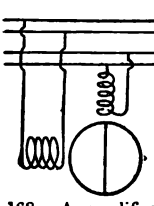

FIG. 168.—A modified type of quarter-phase, variable-speed, commutator motor.

connected to the supply as in Fig. 167, is closed on itself, the armature current being set up by induction from the winding which, in Fig. 167, served as compensating winding.

**312. The polyphase commutator motor with shunt characteristics and with speed control by brush shifting.** The expense of the control arrangements limits the application of variable-speed polyphase motors of

Digitized by Google

types of which that described in Par. 310 (Winter-Eichberg) is representative. It is often considered that brush-shifting types are preferable. One such type which is exploited by the Siemens-Schuckert-Werke and is described by Schenkel on pages 1059 and 14 of The Electrician for Oct. 4 and 11, 1912, is illustrated diagrammatically in Fig. 169. In this figure, the stator windings are represented by $S$. These windings are (in the particular variety illustrated in Fig. 169) supplied directly from the line. A transformer $T$ is interposed between the stator windings $S$ and the rotor brushes $K_1$ and $K_2$. One of these sets of brushes is fixed, and the other is movable. By varying the relative angular positions of $K_1$ and $K_2$ the speed of the motor may be controlled. Each of the two brush gears is fitted with three brush spindles per pair of poles for multiple-circuit rotor windings, or some suitable equivalent for two-circuit rotor windings. These motors have shunt characteristics and are to be distinguished from the Görges motors to which reference has been made in (Par. 294), which have series characteristics.

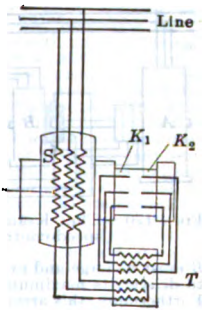

FIG. 169.—Polyphase commutator motor with speed control by brush-shifting.

Such motors are the subject of other articles published by Rüdenberg in the Electrician for April 7 and July 21, 1911, and by Meyer in The Electrician for Feb. 2 and 9, 1911. The former deals with the theory and the latter with the field of application for these motors.

**313. The Déri brush-shifting motor for polyphase circuits.** It is often considered that for obtaining variable speed drive from polyphase circuits, the best plan consists in employing two Déri single-phase motors (of the brush-shifting type already described in Par. 308), coupled to the same shaft and connecting one motor to each phase of a quarter-phase system. This plan has been employed by Messrs. Brown, Boveri & Co. Among other applications of the method may be mentioned some heavy hoisting work. Where the supply is three-phase, the Scott connection of two transformers may be employed to obtain quarter-phase supply for the two motors.

## SYSTEMS OF SPEED CONTROL REQUIRING AUXILIARY COMMUTATING MACHINES

**314. The Krämer system of speed control.** This system is appropriate for applications where the desired range of speed is a moderate percentage of the normal speed. It consists in the employment of a single slip-ring induction motor which at practically synchronous speed carries the entire load. For lower speeds the slip-rings of the rotor of the main motor supply energy to the commutator brushes of an auxiliary motor on the same shaft. The arrangement is indicated diagrammatically in Fig. 170. $A$, the main motor, is of the induction type. $B$, the auxiliary motor, is fitted with a commutator. The counter e.m.f. of the auxiliary motor may be controlled by the position of the points of the secondary of a transformer $C$ from which the connections to the commutator brushes are tapped off. In American practice, however, it is much more usual to make use of a small direct-connected polyphase exciter similar in design to the auxiliary regulating motor. This arrangement (which has been employed by Dr. Meyer-Delius in his designs for the General Electric Co.), is shown in Fig. 171, which is the same as Fig. 170, except that the transformer is replaced by the exciter whose stator is supplied from the slip-rings of the main motor $A$ through a three-phase resistor $D$. Speed control is obtained by manipulation of the resistor and a far larger number of running points is provided than is commercially practicable with the transformer arrangement shown in Fig. 170. The greater the counter e.m.f. supplied by $B$, the lower will be the speed of the rotor of $A$ and consequently also, of the shaft common to $A$ and $B$. The load carried by $B$ is proportional to its counter e.m.f., consequently $B$'s contribution increases as the speed decreases, with the result that the total torque provided by the set increases as the speed decreases. The set thus yields the same total kw. output at low speeds as at normal speed, and this is

Digitized by Google

an important characteristic of the system. It is rarely practicable or desirable to provide for more than 30 per cent. regulation on 60-cycle systems or 50 per cent. regulation on 25-cycle systems, since it is difficult to design the auxiliary motor *B* for good commutation except at low frequencies, and the frequency supplied to its commutator is proportional to the slip of the rotor of *A*. Greater capacities and greater speed ranges can be supplied by these sets the lower the frequency of the system from which they are operated. A disadvantage of the Krämer system relates to the fact that since such sets are usually required for slow-speed work, the auxiliary machine

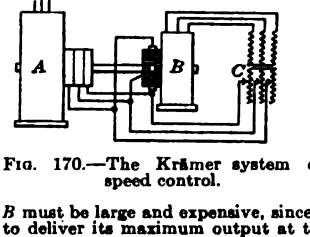

FIG. 170.—The Krämer system of speed control.

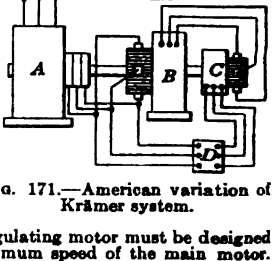

FIG. 171.—American variation of Krämer system.

*B* must be large and expensive, since the regulating motor must be designed to deliver its maximum output at the minimum speed of the main motor. Furthermore, this arrangement necessitates a special design for the regulating motor for each installation where the synchronous speeds of the several main motors differ, even though the total slip energy is the same in each case.

**315. The Scherbius system of speed control.** The arrangement indicated in Fig. 172 is known as the Scherbius system. As in the Krämer system, the main motor *A*, is a simple induction motor with slip-rings. The speed control is effected by an auxiliary set on an independent shaft. This auxiliary set comprises a commutator motor *B*, driving an induction generator

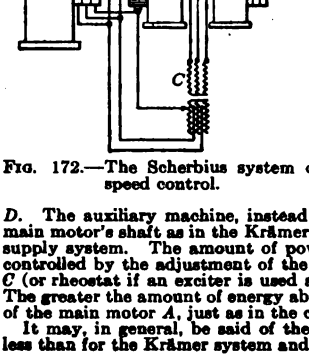

FIG. 172.—The Scherbius system of speed control.

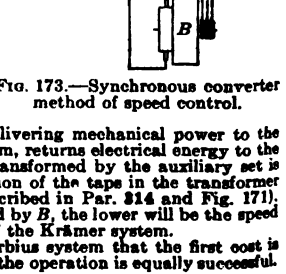

FIG. 173.—Synchronous converter method of speed control.

*D*. The auxiliary machine, instead of delivering mechanical power to the main motor's shaft as in the Krämer system, returns electrical energy to the supply system. The amount of power transformed by the auxiliary set is controlled by the adjustment of the position of the taps in the transformer *C* (or rheostat if an exciter is used as described in Par. 314 and Fig. 171). The greater the amount of energy absorbed by *B*, the lower will be the speed of the main motor *A*, just as in the case of the Krämer system.

It may, in general, be said of the Scherbius system that the first cost is less than for the Krämer system and that the operation is equally successful.

Digitized by Google

The use of an independent high-speed set which can be readily transferred to some other motor if subsequent conditions make the change desirable, is also an advantage. While the Krämer system possesses some advantage under conditions involving the full kilowatts output at the lowest speed and high *synchronous* speed, this advantage often disappears where slow-speed motors are concerned.

**316. Synchronous converter method of speed control.** As stated above, the permissible range of speed regulation with either the Krämer or Scherbius system as described, is limited by the maximum frequency which can be successfully applied to the regulating motor without excessive commutation stresses. In general this frequency should not exceed 18 to 20 cycles or approximately 30 per cent. regulation for 60-cycle systems, and from 10 to 12½ cycles or approximately 50 per cent. regulation for 25-cycle systems. Where greater ranges are required or with units involving a slip energy of 1,000 kw. or more, a synchronous converter and direct-current motor can be successfully substituted for the polyphase commutator motor. In this case (Fig. 173) the slip energy of the main motor *A*, at varying frequency and voltage is transformed to direct current at proportionately varying potential by a synchronous converter *B*. This direct current is then utilised to drive a separately excited shunt motor *C* which may be direct-connected on the shaft of the main motor (Krämer), or (Fig. 173) may form one unit of (*CD*), a two-unit motor-generator (Scherbius), the second unit of which (*D*) is a standard squirrel-cage induction motor which, driven above synchronism, acts as an induction generator and returns to the system the slip energy of the main motor, less, of course, the losses in the rotary and motor generator. This arrangement can be used for practically any range of speed reduction which may be desired. It is of especial advantage on 60-cycle systems, not only because of the freedom from difficulties encountered with the commutator motor when subjected to higher frequencies but also due to the fact that the limitation imposed by the minimum frequency at which the synchronous converter will remain in synchronism is less objectionable on 60-cycle than on 25-cycle equipments. With suitable electrical and mechanical devices for controlling the speed of the synchronous converter during the unstable period of minimum impressed frequency corresponding to the interval between approximately 2 cycles above and below the synchronous speed of the main motor, the speed of the main motor can be raised above normal synchronism by an amount corresponding to the frequency impressed on the slip-rings by the now-inverted synchronous converter.

## PHASE MODIFIERS

**318. Definition.** In order to correct for the lagging current consumed by induction motors and other inductive apparatus, and thus improve the power-factor of a system, apparatus known as phase modifiers (or phase controllers), may be employed. These are of two classes, synchronous, and non-synchronous.

**319. Synchronous phase modifiers (usually termed synchronous condensers)** are of the same general construction as synchronous motors, except that they need not be proportioned to deliver power from the shaft and that their fields should be proportioned for a wide range of excitation.

**320. The usual method of employing synchronous condensers** consists in installing them to float on the line. They are overexcited so as to draw a current leading the pressure by nearly 90 deg. This current neutralises an equal amount of lagging component due to other apparatus on the system, such as induction motors and lightly loaded or unloaded transformers. If designed with the necessary mechanical strength, synchro-

Digitized by Google

nous condensers may simultaneously operate as motors and it is customary to proportion them to thus operate to the extent of a consumption of 70 per cent. of their rated kv-a. They can, when thus operating, be so excited that they also draw from the line, as leading wattless kv-a., 70 per cent. of their rated capacity in kv-a. thus effecting power-factor improvement at the same time that they are serving as motors to deliver mechanical energy. Synchronous condensers are fitted with amortisseur windings to improve their starting qualities and to serve in preventing surging and hunting.

**321. Non-synchronous phase modifiers (or phase controllers).** Several varieties of apparatus customarily called phase advancers, have been developed for use in connection with individual induction motors for the purpose of improving their power-factor. Such apparatus is supplied with very low frequency electricity from the secondary windings of the induction motors. The frequency is that corresponding to the "slip" of the induction motor. Such phase advancers have an inherent characteristic which may conveniently serve to distinguish them from synchronous condensers (Par. **319** and **320**). This characteristic is that they are *not synchronous machines.*

Leblanc was probably earliest in drawing attention to methods of securing phase control by the use of non-synchronous auxiliaries. His proposals may be explained by reference to the accompanying diagrams. In Fig. 174, *AC* and *BD* represent two series-excited machines which, by suitable mechanical means, are driven at some appropriate speed. The field *C* of *AC* and the armature *B* of *BD* are connected in series with phase *N* of the quarter-phase rotor *MN*. Similarly, the field *D* of *BD* and the armature *A* of *AC* are connected in series with the other phase, *M*. Thus the current

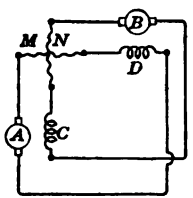

FIG. 174.—Leblanc phase advancer with two armatures and fields.

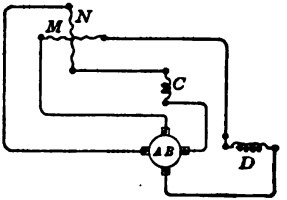

FIG. 175.—Leblanc phase advancer with a single armature.

for exciting the field surrounding each armature is displaced 90 deg. from the current in the phase with which the armature is in series. The armature pressure is consequently 90 deg. displaced from the pressure of the rotor winding with which it is in series. The resultant pressure and current in each rotor circuit, can, by these means, be displaced by any desired amount from the phase relations which would subsist were the rotor windings merely short-circuited on themselves in the customary way. Obviously, the greater the speed at which *A* and *B* are driven and the greater the *m.m.f.* provided by *C* and *D*, the more may the resultant pressures (and, consequently, also the currents) be advanced in phase from the conditions subsisting with a normally short-circuited rotor without a phase advancer.

In practice, however, it is more convenient to employ a single armature, as indicated in Fig. 175, and to supply its commutator (assuming a bipolar design of phase advancer) with four brushes. The armature *AB* (Fig. 175) may be either directly mounted on the motor shaft or it may be driven at a suitable speed by an auxiliary motor. The currents supplied to the brushes will be of the low frequency corresponding to the slip of the rotor *MN* of the induction motor whose power-factor it is desired to improve. Fig. 176 differs from Fig. 175 simply in that a field structure is indicated surrounding the armature *AB*, and also in the subdivision of the field windings *C* and *D* among the four poles. It must be noted that although, geometrically speaking there are four poles, magnetically considered, it is a bi-polar design. Similarly, as shown in Fig. 177, a three-phase bi-polar advancer

Digitized by Google

has three geometric poles. The windings are usually distributed in slots at the inner periphery of the stator instead of being arranged on salient poles as indicated diagrammatically in Fig. 176.

**322. The Miles Walker phase advancer.** In the phase advancer developed by Prof. Miles Walker, a compensating winding is added as shown in Fig. 178 in which $E_1E_2E_3$ are the three exciting windings and $C_1C_2C_3$ the three compensating windings. The exciting windings $E$ are (for a bi-polar design) usually concentrated in three large equi-distant slots in the stator core, while the compensating windings $C$ are distributed in many small slots in order to neutralise (or slightly overneutralize), the *m.m.f.* of the rotor winding. It is claimed for this type that it possesses features specially conducive to ready adjustment and good commutation.

**323. Omission of stator windings in non-synchronous phase advancers.** Leblanc's original proposals showed examples of phase advancers, in which no windings were provided on the stator. Such a plan as applied to a three-phase four-pole advancer, is shown diagrammatically in Fig. 179. The recesses opposite the brushes are provided for improving the commutation. Scherbius in some phase advancers built by Messrs

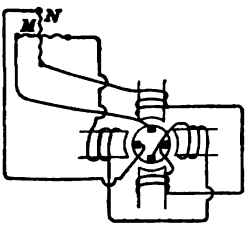

FIG. 176.

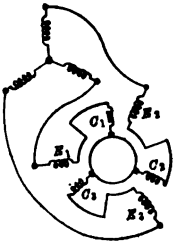

FIG. 178.

FIG. 176.—Alternative method of diagrammatic representation of Leblanc single-armature phase advancer.

FIG. 177.—Diagrammatic representation of phase advancer wound for three phases.

FIG. 178.—Miles Walker phase advancer with exciting and compensating windings on the stator.

Brown-Boveri & Co. has employed this plan of omitting exciting windings from the stator. But *compensating* windings are usually fitted on the stator in phase advancers for large slow-speed induction motors.

**324. An understanding of the underlying idea of the non-synchronous phase advancer** (Par. 321) may also be obtained by first considering that the low-frequency currents, from the secondary of the main motor, flow into the rotor of the phase advancer while it is at rest. Under these conditions the current will *lag*, since the rotor circuits are inductive. But if the rotor is driven in the direction of the magnetic field which is circulating in it and which has been occasioned by the *m.m.f.* of the low-frequency currents from the secondary of the main motor, and if the speed at which it is driven is exactly that of the rotating field, then there is a state of relative rest between the field and the rotor, and the latter's windings are non-inductive and occasion *neither lag nor lead*. If the rotor is driven at higher speeds, the rotor circuits again become inductive but introduce *leading* electromotive forces into the secondary circuits of the main motor.

**325. Scherbius phase advancers with entire omission of stator.** Scherbius has devised a phase advancer consisting simply in a rotor with its windings completely embedded below the surface. Diagrammatically such a phase advancer and its connections reduce to the simple arrangement shown in Fig. 180, in which $A$ represents the rotor of the induction

Digitized by Google

motor with its windings connected to the brushes of the Scherbius phase advancer *B*. The latter is usually mounted directly on the shaft of the main motor. Thus the scheme reduces to the simple proposition of establishing a field in the magnetic circuit of *B* by means of the *m.m.f.* of the current supplied to its brushes from *A*. This field rotates very slowly in space since the frequency of the rotor currents is small. But *B* is rotated mechanically at the high speed of the rotor *A* and consequently the windings on *B* rotate much faster than the magnetic field in *B*, and in cutting through this field they set up an e.m.f. which, combined with the e.m.f. in the main rotor occasions an advance in the phase of the currents in the rotor circuits and improves the power-factor of the motor.

In a letter published in *The Electrician*, July 12, 1912, page 582, Scherbius states that both theory and practice support the idea that a mere ring is
